Step 3: Apply weights to the leaves. For each leaf, assign qualitative values (e.g., high, medium, low) for adversary risk, impediment to access, cost, and motivation (added for IV but applies to EV too). For example, an adversary sending an e-mail containing a virus attachment has low risk (probability of being identified is low), medium impediment to access (probability of the victim not opening the attachment and unleashing the virus is medium), low cost (cost to the adversary to create the virus e-mail is low), and high motivation (the adversary wants to cause as much disruption as possible). These values can be represented as a 4-tuple (L, M, L, H) where L, M, H stand for low, medium, high respectively, and the left most position in the tuple is risk, followed by impediment to access, followed by cost, and finally motivation. As another example, an adversary who is an insider with authorized access to private information and who wants to steal that information may be weighted as (L, L, L, H), that is, the adversary has low risk (probability of being caught is low), low impediment to access (adversary already has authorized access), low cost (cost to the adversary to make a copy of the information is low), and high motivation (the financial value of the information is very high). The provider with a vulnerability weighting of (L, L, L, H) has to think seriously about adding provisions to mitigate the vulnerability, as this weighting means that there is a very high probability that an attack using this vulnerability will occur.

Step 4: Prune the tree so that only exploitable leaves remain. Count the number of such leaves or vulnerabilities. Prune by deciding what levels (high, medium, low) of risk, impediment to access, cost, and motivation the provider is willing to have associated with the remaining vulnerabilities. These levels will determine which vulnerabilities are exploitable, and therefore add to the provider's cost to install countermeasures (provisions against privacy policy violations). Providers may choose to spend more or less on countermeasures by setting levels that result in less or more, respectively, leaves being pruned. For example, setting a level of (H, M, H, L) would prune all leaves with matching levels as well as all leaves that match (H, H, H, L) since (H, H, H, L) implies an even lower probability of attack than (H, M, H, L).

After pruning the tree, count the number *n* of exploitable leaves or vulnerabilities that remain.

Step 5: Determine if countermeasures are in place for the vulnerabilities found in Step 4. Count the number of these vulnerabilities so mitigated. Examine what countermeasures are in place for the vulnerabilities found in Step 4 and count the number of vulnerabilities *q* that have countermeasures. This step requires knowledge and experience of which countermeasures can be applied in a given situation.

Example Calculation of *n* and *q* Using Threat Analysis

Consider the automatic bank teller machine (ATM) that is ubiquitous in most shopping malls. There are many possible threats against an ATM but let us consider one threat: the threat of an adversary obtaining a bank customer's private account information for using an ATM. A possible attack tree for this threat is as follows:

1. Adversary obtaining a customer's account information for using an ATM
   - 1.1. Adversary holds up customer obtaining customer's access card and pin
   - 1.2. Adversary installs an ATM front end that secretly captures the customer's card info and pin
     - 1.2.1. The captured information is stored in the front end
     - 1.2.2. The captured information is transmitted to the adversary
   - 1.3. Adversary finds customer's access card and has a way of discovering the pin
     - 1.3.1. Adversary guesses the pin based on researching the customer
     - 1.3.2. Adversary uses a dictionary attack to discover the pin
     - 1.3.3. Adversary uses social engineering to obtain the pin

It can be seen that the root of this attack tree (1) contains the threat and the branches are attack paths that are alternative ways to realize the threat. For example, the path (1, 1.3, 1.3.3) is a legitimate attack path. The leaves of this tree are the nodes 1.1, 1.2.1, 1.2.2, 1.3.1, 1.3.2, and 1.3.3. As an example of applying weights to this tree, the leaf 1.1 has very high risk to the attacker, the impediments to access is low (customers with ATM cards are plentiful), the cost to the attacker to carry out the attack is low (e.g., fake gun), and the attacker's motivation is high (attacker is desperate for money). Because the risk to the attacker is very high, the path (1, 1.1) may be pruned from the tree. Similarly, the leaf 1.2.1 may be unlikely since the risk to the adversary is high (the front end could be discovered before the captured data could be retrieved). As well, the leaves 1.3.1 and 1.3.2 are infeasible due to the fact that the ATM captures the card and flags the account after a fixed number of pin entries. After pruning the unlikely attack paths from the tree, the tree that remains is as follows:

1. Adversary gaining access to customer's account information for using an ATM
   - 1.2. Adversary installs an ATM front end that secretly captures the customer's card info and pin
     - 1.2.2 The captured information is transmitted to the adversary
   - 1.3. Adversary finds customer's access card and has a way of discovering the pin
     - 1.3.3 Adversary uses social engineering to obtain the pin

Thus there are two likely attack paths: (1, 1.2, 1.2.2) and (1, 1.3, 1.3.3). A countermeasure for (1, 1.2, 1.2.2) would be to disallow any possibility of a front end being installed to an ATM, perhaps by physically redesigning the ATM or by frequent random inspections and monitoring. Suppose that this countermeasure is not yet in place. A countermeasure for (1, 1.3, 1.3.3) would be to strengthen procedures so that social engineering cannot succeed (e.g., no one is allowed to give out the customer's pin no matter what the circumstance). Suppose that this countermeasure is already in place. Then for this example, $e_e = q/n = 1/2$.

APPLICATION EXAMPLE

Consider a Web service, such as Easy123Drugs.com, that is an online drug store (e.g., Walgreens.com). Easy123Drugs is a multiprovider service that makes use of two business Web services:

an online payment service PayAsYouLikeIt.com (e.g., Paypal.com) and an accounting service AccountingAsNeeded.com (e.g., cbiz.com). Suppose Easy123Drugs, PayAsYouLikeIt, and AccountingAsNeeded (all fictitious names with no hits on Google) are all Web services that are based on the service-oriented architecture (SOA) (O'Neill et al., 2003), employing XML-based protocols (not necessarily the case for the real life examples cited here). Due to space limitations in this article, the details regarding UDDI lookup and service binding via SOAP and WSDL (O'Neill et al., 2003) will not be described here. It is assumed that these initialization steps occur as required. Figure 5 shows the network architecture of these services after service lookup and binding have occurred. The dashed lines in Figure 5 indicate logical communication channels.

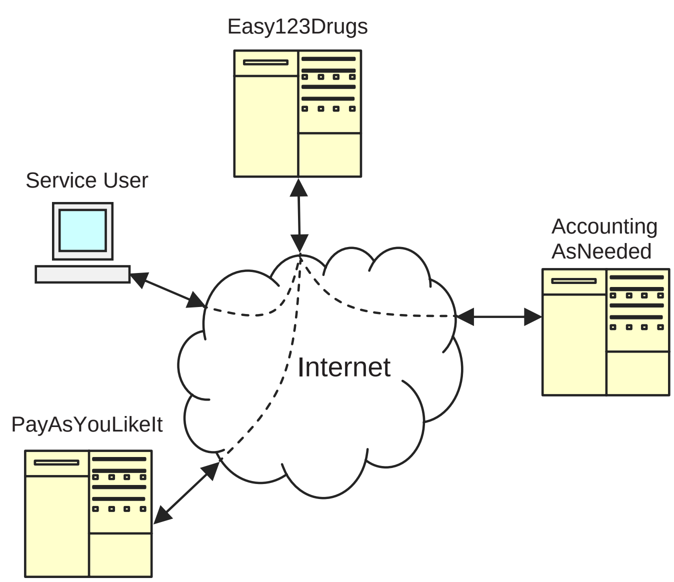
Table 3 shows the service user's private information required by each provider. The user provides required private information to Easy123Drugs once the user's privacy policy has been agreed to by Easy123Drugs. Easy123Drugs then discloses the user's private information to PayAsYouLikeIt and AccountingAsNeeded according to the user's privacy policy and after these second providers agreed with Easy123Drug's privacy policy (which contains the user's privacy preferences with regard to the information disclosed).

Easy123Drugs.com decides to hire a privacy auditor, certified to apply the above estimation methods, to estimate its capability of protecting privacy, with the intention of using the results in its advertising (assuming the results are good).

Calculation of *m* and *p*

To determine values for *m* and *p*, the auditor puts together a team to do a PIA for each service. Assume that each service stores the user's private data in a database and that the internal threats to the user's private data are about the same for each service. It is then possible to do one PIA that applies to all three services. However, the countermeasures in place are likely to be different for each service. The PIA team traces the flow of private information as shown by the PIP in Figure 6. In this figure, the customer's private

Figure 5. Network architecture of Easy123Drugs service



information (Table 3) arrives first at Easy123Drugs where it is received (first triangle), stored (first square), and processed, including forwarding some of the information to PayAsYouLikeIt and AccountingAsNeeded (second triangle). Similarly, selected information (Table 3) is received at PayAsYouLikeIt and AccountingAsNeeded where it is stored and processed.

The PIA team performs the PIA and uncovers IV vulnerabilities that fall under malicious attacks and unintentional disclosures, as follows:

Malicious attacks:

a. Attacker steals the data for sale to an outside interest.
b. Attacker uses the data for social engineering a personal goal.
c. Attacker passes the data to a friend as a favor.
d. Attacker passes the data to a competitor free of charge.

Unintentional disclosure:

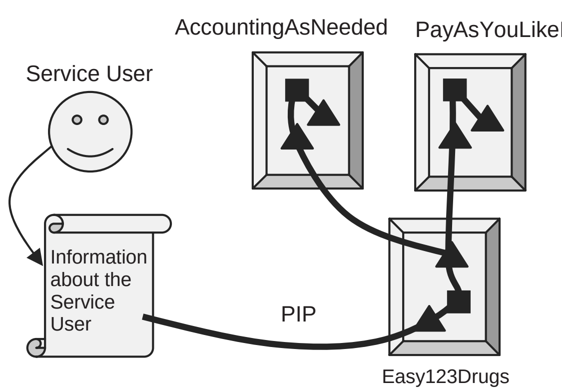
e. The data are inadvertently disclosed in an e-mail.
f. The data are inadvertently disclosed in a conversation.
g. A laptop containing the data is stolen.
h. Paper copies of the data are misplaced.
i. Paper copies of the data are left in a public area in plain view.
j. The data's retention time expires unknown to any staff.

For the malicious attacks, the PIA analysis considered the risks to the attacker and the attacker's motivation to carry out the attack. Due to the possibility that the source of the data could be traced, together with the fact that the data themselves are of relative low value (e.g., not military secrets), the risks to the attacker for a) and d) were considered very high and therefore these attacks are unlikely to occur. On the other hand, the risks to the attacker for b) and c) were considered low with the attacker's motivation high to medium since these attacks involve personal goals and relationships. Thus b) and c) were considered serious vulnerabilities that needed attention. Similarly, due to the fact that staff had undergone thorough training in safeguarding their laptops and paper copies, only vulnerabilities e), f), and j) were considered serious, requiring attention. Thus, the PIA identified five IV vulnerabilities that can be assigned to each provider as follows: Easy123Drugs gets the full $m=5$ vulnerabilities,

Table 3. Private information required

Web Service Provider	Private Information Required
Easy123Drugs	User's name, drug name and quantity, doctor's name and authorization, user's address
PayAsYouLikeIt	User's name, credit card details
AccountingAs Needed	User's name, drug name, doctor's name, quantity of drug sold, price paid by user, user's address

Figure 6. PIP for Easy123Drugs; squares indicate storage points, triangles indicate use



PayAsYouLikeIt gets *m=4* vulnerabilities since it has a retention time tracking mechanism, and AccountingAsNeeded gets *m=2* vulnerabilities since it has the retention time tracking and the remaining unintentional vulnerabilities do not apply to accountants because they are trained in safe data handling procedures.

Suppose the PIA found that Easy123Drugs and PayAsYouLikeIt have countermeasures in place against all vulnerabilities except for b) (the exact nature of the countermeasures is not important for this example). Suppose that AccountingAsNeeded has countermeasures in place against both of its vulnerabilities. Therefore, *p=4* for Easy123Drugs, *p=3* for PayAsYouLikeIt, and *p=2* for AccountingAsNeeded. Table 4 contains the values for *m* and *p.*

Calculation of *n* and *q*

The threat analysis described above is now applied to calculate *n* and *q* for each provider. Again, assume that each service stores the user's private data in a database. Assume also that the external threats to the user's private data are the same for each service. It is then possible to do one threat analysis that applies to all three services. However, the countermeasures in place are likely to be different for each service. Following the steps mentioned above,

Step 1: Using Figure 5 to visualize possible threats against the user's data, the main EV threat that includes most other EV threats is: "outside attacker compromises the user's private data."

Steps 2 and 3: The attack tree and weights are as follows.

1. Outside attacker compromises the user's private data.
   - 1.1. Attacker steals the user's private data.
     - 1.1.1. Attacker launches a man-in-the-middle attack on a communication channel to eavesdrop. (L, L, L, M)
     - 1.1.2. Attacker launches a Trojan horse attack on a provider's system. (L, L, L, M)
     - 1.1.3. Attacker launches a phishing attack on the user. (L, L, M, H)
     - 1.1.4. Attacker uses social engineering to deceive a provider staff member into giving out the user's data. (M, M, L, M)
     - 1.1.5. Attacker breaks into a provider's premises to steal the user's data. (H, H, M, H)
     - 1.1.6. Attacker mugs a provider employee and steals the employee's access card to enter a provider's premises and steal the user's data. (H, H, L, M)
   - 1.2. Attacker modifies the user's private data.
     - 1.2.1. Attacker launches a man-in-the-middle attack on a communication channel to modify the user's data. (L, L, L, M)

Table 4. Calculation of E_1 and E_2

Service	*m*	*p*	*n*	*q*	$E_1 = (p + q) / (m+ n)$	$e_i=p/m$	$e_e=q/n$	$E_2=(e_i, e_e)$ (%)
Easy123Drugs	5	4	7	6	.83	.80	.86	(80, 86)
PayAsYouLikeIt	4	3	6	5	.80	.75	.83	(75, 83)
AccountingAsNeeded	2	2	6	5	.88	1.0	.83	(100, 83)

1.2.2. Attacker launches a virus attack on a provider's system. (L, L, L, M)
1.2.3. Attacker uses social engineering to deceive a provider staff member into giving the attacker access to modify the user's data. (M, M, L, M)
1.2.4. Attacker breaks into a provider's premises to modify the user's data. (H, H, M, H)
1.2.5. Attacker mugs a provider employee and steals the employee's access card to enter a provider's premises and modify the user's data. (H, H, L, M)

Some of the reasoning behind the motivation weightings are: vulnerability 1.1.3 has motivation H as phishing is a quick way to obtain private data such as bank account information; vulnerabilities 1.1.5 and 1.2.4 have motivation H because breaking and entering is a serious crime and the attacker must be highly motivated before contemplating such an action.

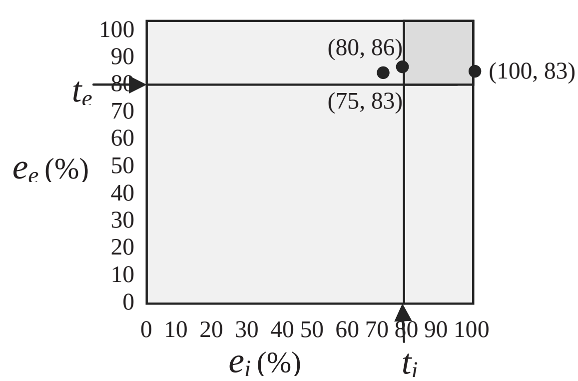
Step 4: The attack tree can be pruned by removing attack paths that are weighted with at least two Hs other than for motivation. Applying this criterion removes the attack paths (1, 1.1, 1.1.5), (1, 1.1, 1.1.6), (1, 1.2, 1.2.4), and (1, 1.2, 1.2.5). This leaves seven vulnerabilities that can be assigned to each provider as follows: Easy123Drugs gets the full $n=7$ vulnerabilities, PayAsYouLikeIt gets $n=6$ vulnerabilities since the phishing attack really only applies to Easy123Drugs, and AccountingAsNeeded gets $n=6$ vulnerabilities, again because the phishing attack does not apply to it. Note that the man-in-the-middle attack on a channel is double counted when it is considered a vulnerability for the provider at each end of the channel. However, this double counting is remedied by the countermeasure, which removes the vulnerability from both providers.

Step 5: Suppose that Easy123Drugs has countermeasures in place against all vulnerabilities except phishing (again, the exact nature of the countermeasures is not important here). Suppose also that PayAsYouLikeIt and AccountingAsNeeded have countermeasures in place against all vulnerabilities except social engineering. Therefore, $q=6$ for Easy123Drugs, $q=5$ for PayAsYouLikeIt, and $q=5$ for AccountingAsNeeded. Table 4 contains the values for n and q as well as the calculated results for E_1 and E_2.

Suppose the minimum acceptable threshold for E_1 is $t=85$. Then the results (Table 4) show that AccountingAsNeeded is the only provider that passes E_1 evaluation. The other providers need to add more provisions against IV or EV in order to pass. They may choose to add provisions that are easy to install or that are the least expensive. It can also be observed that AccountingAsNeeded is the most capable of protecting privacy whereas PayAsYouLikeIt is the least capable. However, comparing these providers to select which one to use based on E_1 is not feasible since their services are all different.

Plotting E_2 for minimum acceptable thresholds $t_i=80$ and $t_e=80$ according to Figure 4 gives Figure 7, which shows that each service passes E_2 evaluation except for PayAsYouLikeIt (with $E_2 = (75, 83)$).

Figure 7. Plots of E_2 for the example services



PayAsYouLikeIt is deficient in provisions for IV. For Easy123Drugs to pass E_2 evaluation as a first (i.e., multiprovider) service, PayAsYouLikeIt would have to add provisions against IV vulnerability b) above (see the chained rule above). Had thresholds t_i and t_e both been set to 90, no provider would pass. In this case, development would need to install a countermeasure against phishing, employees would need to be trained to resist social engineering, and provisions against IV would need to be added for providers that lacked these countermeasures. This shows that estimates of privacy protection capability can be used as a tool by development or management (e.g., to require social engineering training) in order to achieve predefined goals of privacy protection.

To consider the effects of past violations, suppose that Easy123Drugs had a disgruntled employee who 2 years ago passed private information to the news media that a certain famous actress was purchasing cancer drugs. Suppose that this made headlines and as a result, Easy123Drugs was sued by the actress and had to pay her 2 million dollars in damages. Easy123Drugs has since made policy changes to ensure that employees feel that they are treated fairly by the company, including the hiring of an ombudsman and a counselor. This past violation can thus be considered of high severity with some new measures installed post violation in order to avoid such violations in the future. Based on Easy123Drugs' response to this past violation, Table 1 shows *high support* (right-most column under profit-oriented service provider) for the provider's future privacy protection capability. In other words, Easy123Drugs will be highly motivated to make sure that it is capable of protecting privacy.

RELATED WORK

The literature appears empty on works dealing directly with estimates of a service provider's capability to protect privacy. Only works that are indirectly related were found. These refer to the economics of security or the economics of privacy (see http://www.cl.cam.ac.uk/~rja14/econsec.html - available as of May 6, 2006). These authors hold the view that the lack of security or the lack of privacy are not due to the lack of technological solutions but rather are due to other (perhaps perverse) considerations such as economics and profitability. This work differs from that view in that the proposed approach evaluates the capability to protect privacy by counting provisions against privacy violations that ARE in place, NOT WHY they may or may not be in place. Nevertheless, their view is valuable in understanding how to improve privacy protection, and is thus seen as complementary to this work. Another area that is indirectly related to this work concerns privacy audits (Enright, n.d.) and privacy risk (or impact) assessment (or analysis) (Treasury Board of Canada, n.d.). As explained above, the latter consists of methods or guidelines on how to identify vulnerabilities or risks in managing private information in order to comply with privacy legislation. We applied a privacy impact assessment to find IV vulnerabilities. In general, these and other methods in the privacy audit domain can be introduced into this work to better understand risks that lead to IV and EV. For example, they could help identify a new class of privacy vulnerabilities. Alternatively, this work could be used in a privacy audit to obtain more comprehensive results, but further research in this regard is needed. Of course, the area of threat analysis is indirectly related to this work (although we applied threat analysis, it is still only indirectly related as a means to an end). Threat analysis has been used for many years and several forms of it exist. The different forms can differ in how weighting is done (as this work too has introduced motivation into the weighting), how a threat is defined, how many people should be involved in carrying out a threat analysis, how much detail is recorded, and so on. Other authors who have recently written on threat analysis include Karger (2006) and

Rippon (2006). An older reference for basic threat analysis is Bauer (2002). Finally, other indirectly related work consists of the entire area of privacy enhancing technologies, some of which were mentioned above as provisions against IV. Also in this category is the work allowing Web sites to specify their privacy policies using platform for privacy preferences (P3P) (W3C, n.d.) to allow for automatic user agent interpretation of a privacy policy, and the machine readable privacy policy languages of P3P preference exchange language (APPEL) (W3C, 2002) and enterprise privacy authorization language (EPAL) (IBM, 2003).

EVALUATION OF APPROACH

Since, as far as can be determined, this work is new, an evaluation of the proposed approach by direct comparisons to other similar works is not possible. Therefore, this evaluation is conducted by considering how well the approach can accomplish its stated purpose by considering in turn the suitability of each component of the approach or how well a component can perform its function.

The goal of the proposed approach is to evaluate the privacy protection capability of a service provider. This is achieved by considering a provider's installed provisions against violations of privacy policy and the provider's history of past violations, if any. It was postulated that a past violation under the "right" circumstances (i.e., profit-oriented provider, sizable violation known to the public, additional provisions to prevent future violations installed after the past violation) would motivate the provider to improve its capability to protect privacy. The approach consists of three components: i) a model of privacy protection in terms of privacy policy violations, ii) definition of estimates of a provider's capability to protect privacy, and iii) methods for calculating the estimates.

The model of privacy protection is based on preventing internal and external violations against privacy policies. This model requires that personal privacy policies exist in a provider organization and that the provider has agreed to uphold them. This requirement is reasonable since most online organizations today have their own privacy policies. Today, personal privacy policies are in the minority when compared to organizational privacy policies, but personal privacy policies should increase with time, in line with the increasing demand for organizations to respect personal privacy preferences.

The definitions of the estimates appear to be straightforward, and follow the model of privacy protection in terms of counting provisions against violations. Moreover, they provide not only a useful single number (E_1) comparison between different providers of similar services, but also an easy graphical visualization (by plotting E_2) of where a provider stands in terms of its capability to protect against IV and EV separately (Figure 4). The advantage of straight forward estimates should not be underestimated, since they need to be understandable by the general public, and "the simpler, the better."

The proposed methods for calculating the estimates naturally have strengths and weaknesses. Strengths include: a) both PIA and threat analysis are well known and have been practiced for years; b) both are well documented in the literature; and c) PIA is an approach recommended by privacy authorities. Weaknesses include: a) PIA is a rather long and involved procedure requiring management support; b) the questionnaire for identifying vulnerabilities that could lead to malicious IV requires testing to confirm its validity; c) PIA results may depend on the skill and knowledge of the people involved with doing the PIA; d) the results from threat analysis may depend on the skill and knowledge of the threat analyst; and e) in the threat analysis, the subjective weighting of the leaves and the pruning criterion are not as exact as one would like (the pruning criterion depends partly on how much money the organization is willing to spend on countermeasures, and links back to the economics of security related work mentioned above). Despite the weaknesses of the threat analysis, it is an accepted procedure and has been applied in many situations to assess threats. The threat analysis procedure may be improved with further research, or the application of other methods (such as privacy audit methods mentioned above) can be incorporated. To help mitigate weaknesses a), c), d), and to some extent e), we suggest that the methods be applied by a separate, impartial firm specialized in performing PIA and threat analysis. To go further, guidelines on applying the methods could be standardized by a privacy authority, and only firms certified by the same authority may apply the methods. This would ensure that the calculation of the estimates of capability to protect privacy is done fairly and consistently for each provider. This approach of using certified third parties to evaluate something is not new; it has been applied successfully to determine conformance to the ISO 9000 series of standards (International Organization for Standardization, n.d.) as well as to evaluating ratings relative to the capability maturity model integration (CMMI) (Carnegie Mellon Software Engineering Institute, n.d.) for software producers.

The accuracy of the proposed estimates may be another point of contention. It may be argued that a simple count of provisions against IV or EV is not enough; actual protection of privacy depends on the *effectiveness* of these provisions. The author agrees that if effectiveness could be incorporated into the estimates, the results would be more accurate. However, effectiveness itself depends on many factors, such as the capability of the provision to do what it is supposed to do, how the provision is implemented, the environment in which the provision operates, and so on. The decision was made to avoid these complexities, opting instead for straightforward easy-to-calculate estimates. The author believes that this is reasonable, trusting that providers would not throw money away on ineffective provisions.

The idea that under the “right” circumstances (see second paragraph in this section), past violations would motivate a provider to protect privacy in the future is untested, as noted above under “Past Violations.” Nevertheless, the idea seems intuitively reasonable. Testing this idea is left for future work.

Finally, it should be pointed out that a provider that is estimated to have the capability to protect privacy may still not do so in reality. For instance, this may happen if key people responsible for maintaining privacy enhancing technologies leave the provider. Another reason may be that the provider perceives goals other than privacy protection as having more immediate higher priority, such as spending money on new production capabilities rather than hiring people needed to maintain privacy enhancing technologies. Still a third reason may be that the provider has undergone a restructuring (e.g., acquired by another provider) and the new people in charge have different priorities. Incorporating such almost always unforeseeable changes into a method for likelihood estimation of privacy policy compliance would be very complicated and difficult. Nevertheless, it may be assumed that in general, providers that have the capability to protect privacy will do so, especially if failure to protect privacy means stiff legal penalties. Stiff legal penalties for failure to protect privacy have already been implemented (U.S. Government, n.d.).

In summary, the author believes that the approach proposed in this work is a reasonable first attempt at evaluating the capability of a provider to protect user privacy. Key challenges regarding the potentially subjective nature of the threat analysis may be reduced with further research.

CONCLUSION AND FUTURE RESEARCH

This work has proposed estimates for evaluating a provider’s capability to protect privacy and illustrated the calculation of the estimates using an example of a multiprovider service. The estimates serve at least four important functions: 1) they make it possible for providers to be challenged if their capability for protecting privacy is perceived to be inadequate; 2) they allow for enforceable privacy protection legislation requiring providers to ensure that they can meet privacy policy compliance requirements; 3) they allow customers to compare providers in terms of their capability to protect privacy when deciding which provider to use for a particular service; and 4) they enable the providers themselves to improve their services by showing them i) where they stand in terms of privacy protection capability against IV and EV and ii) what provisions against IV or EV they need to add in order to improve their standing.

It is envisioned that providers will want to advertise their estimates to show that they exceed standard privacy protection capability thresholds (which could be standardized by an international body) in the same way that they advertise conformance to ISO 9000. This could encourage providers to achieve higher levels of privacy protection, which in turn could lead to greater public trust in Web service providers resulting in increased commerce.

Future research includes improving the methods for calculating the estimates, such as increasing the effectiveness of the procedure for threat analysis by automating it and making it more foolproof, as well as investigating other possible estimates of capability to protect privacy.

ACKNOWLEDGMENT

The author gratefully acknowledges the support of the National Research Council Canada for this work.

Chapter 7.7
Privacy Concerns for Web Logging Data

Kirstie Hawkey
University of British Columbia, Canada

ABSTRACT

This chapter examines two aspects of privacy concerns that must be considered when conducting studies that include the collection of Web logging data. After providing background about privacy concerns, we first address the standard privacy issues when dealing with participant data. These include privacy implications of releasing data, methods of safeguarding data, and issues encountered with re-use of data. Second, the impact of data collection techniques on a researcher's ability to capture natural user behaviors is discussed. Key recommendations are offered about how to enhance participant privacy when collecting Web logging data so as to encourage these natural behaviors. The author hopes that understanding the privacy issues associated with the logging of user actions on the Web will assist researchers as they evaluate the tradeoffs inherent between the type of logging conducted, the richness of the data gathered, and the naturalness of captured user behavior.

INTRODUCTION

Privacy is an important consideration when conducting research that utilizes Web logs for the capture and analysis of user behaviors. Two aspects of privacy will be discussed in this chapter. First, it is important that governmental regulations, such as the Personal Information Protection and Electronic Documents Act (PIPEDA) in Canada, or organizational regulations, such as a university's local research ethics board (REB) policies, are met. These regulations will dictate requirements for the storage and safeguarding of participant data as well as the use, re-use, and transfer of that data. Secondly, researchers may also find that providing privacy enhancing mechanisms for participants can impact the success of a study. Privacy assurances can ease study recruitment and encourage natural Web browsing behaviors. This is particularly important when capturing rich behavioral data beyond that which is ordinarily recorded in server transaction logs, as is generally the case for client-side logging. It is this second aspect of privacy that will be the primary focus of this chapter.

DOI: 10.4018/978-1-59904-974-8.ch005

There are privacy concerns associated with viewing and releasing Web browsing data. Web browsers are typically used for a wide variety of tasks, both personal and work related (Hawkey & Inkpen, 2006a). The potentially sensitive information that may be visible within Web browsers and in data logs is tightly integrated with a person's actions within the Web browser (Lederer, Hong, Dey, & Landay, 2004). Increasingly the Internet has become a mechanism by which people can engage in activities to support their emotional needs such as surfing the Web, visiting personal support forums, blogging, and investigating health concerns (Westin, 2003). Content captured within Web browsers or on server logs may therefore include such sensitive items as socially inappropriate activities, confidential business items, and personal activities conducted on company time, as well as more neutral items such as situation-appropriate content (e.g., weather information). Visual privacy issues have been investigated with respect to traces of prior Web browsing activity visible within Web browsers during co-located collaboration (Hawkey, 2007; Hawkey & Inkpen, 2006b). Dispositional variables, such as age, computer experience, and inherent privacy concerns, combine with situational variables, such as device and location, to create contextual privacy concerns. Within each location, the social norms and Web usage policies, role of the person, and potential viewers of the display and users of the device impact both the Web browsing behaviors and privacy comfort levels in a given situation. The impacted Web browsing behaviors include both the Web sites visited, as well as convenience feature usage such as history settings and auto completes. Furthermore, most participants reported taking actions to further limit which traces are potentially visible if given advanced warning of collaboration.

Recently the sensitivity of search terms has been a topic in the mainstream news. In August 2006, AOL released the search terms used by 658,000 anonymous users over a three month period (McCullagh, 2006). These search terms revealed a great deal about the interests of AOL's users, and their release was considered to be a privacy violation. Even though only a few of the users were able to be identified by combining information found within the search terms they used, AOL soon removed the data from public access. This data highlighted the breadth of search terms with respect to content sensitivity as well as how much the terms could reveal about the users in terms of their concerns and personal activities.

In addition to taking actions to guard visual privacy within Web browsers, users may also take steps to guard the transmission of their personal information online. When concerned about privacy as they interact on the Web, users may opt to mask their identities by using a proxy server or other anonymizing (Cranor, 1999). The Platform for Privacy Preferences Project (www.w3.org/P3P/) has developed standards that facilitate user awareness of the privacy policies that govern the use of their personal information at participating websites. Research into online privacy generally examines issues concerning the transfer of personal data to business or governmental entities; the relationships are between consumers and corporations. This may be quite different from the privacy concerns associated with others viewing traces of previous Web browsing activity, as in the case of logged Web browsing data in a research context. Although in both cases personal information may be viewed, there are differences in the nature of the relationship to the viewer of the information. When the viewers of the captured information are not anonymous but are known to the user, privacy concerns may be heightened (Lederer, Mankoff, & Dey, 2003).

Field research theoretically allows the study of actual behaviors in a realistic environment. However, the act of observing or recording participants' personal interactions may cause them to alter those behaviors (McGrath, 1995). This is often referred to as the Hawthorne Effect. For example, behaviors deemed to be socially inappropriate (Fisher,

1993) may be avoided during the period of the study. As well, participants may be unwilling to have logging software installed that may record personal interactions, particularly if that software logs data across applications. Software (e.g., a keystroke logger, or custom web browser) that has the potential of capturing user names and passwords may cause additional concerns (Weinreich, Obendorf, Herder, & Mayer, 2006). Privacy preserving mechanisms can help encourage participants to engage in their natural Web browsing behaviors and activities while allowing researchers to study the behaviors of interest. Appropriate methods of mitigating participants' privacy concerns depend on the research questions and the experimental logging environment in use.

The objectives of this chapter are to provide researchers with an understanding of the privacy issues associated with the logging of Web activity. Background will be provided in the areas of privacy theory in general and privacy concerns for Web browsing data in particular. It is important that privacy concerns are understood so that observational effects on behavior can be reduced during studies. Furthermore, the tradeoffs between participants' privacy and the collection of rich, yet natural data for various logging techniques will be discussed. Finally, guidelines for mitigating participants' privacy concerns during studies investigating Web behaviors will be presented.

BACKGROUND

General Privacy Theory

Westin (2003) defines individual privacy as "the claim of an individual to determine what information about himself or herself should be known to others." Over the past forty years, Westin has primarily dealt with consumer privacy rights, such as when personal information can be collected and how others can make use of the information. Westin also discusses how individuals seek a balance between maintaining privacy and fulfilling a need for communication and disclosure. How an individual manages this tradeoff depends on their personal situation including their family life, education, social class, and psychological composition. Furthermore, Westin states that an individual's privacy needs are highly contextual and continually shift depending on situational events.

This contextual nature of privacy is well established in the literature. Goffman (1959) first introduced the need to project different personas or faces during social interactions. The face presented in any given situation depends not only on the current audience but also on the current conditions. The combination of audience and situation determines how much and what information will be disclosed. Furthermore, as discussed by Palen and Dourish (2003), people can have many roles between which they fluidly move and can act in multiple capacities, often simultaneously. For example, one may act as an individual, a family member, and a representative of an organization. A person's role can influence their sense as to whether their behaviors would be considered socially acceptable. If information is conveyed that is out of character for the person's current role, the boundaries that have been maintained can collapse creating opportunities for social, bodily, emotional, and financial harm (Phillips, 2002). Lederer et al. (2003) discuss how activities convey the essence of a persona. Knowledge of an individual's prior activities is more sensitive when their identity is known as the activities can reveal hidden personae.

Privacy Concerns for Web Browsing Data

Web users conduct a wide range of activities within their Web browsers, resulting in visited web pages with a variety of content sensitivity (Hawkey & Inkpen, 2006a). Teltzrow and Kobsa (2004) summarized thirty published consumer surveys and studies investigating Internet privacy. Results consistently revealed that the majority of Internet users are concerned about the security of personal information as well as concerned about being tracked on the Internet, with a lesser amount being concerned that someone might know what websites they visited. Two field studies have specifically examined visual privacy concerns for visited Web pages. For the first study, conducted in 2004 (Hawkey & Inkpen, 2005), 42% of visited pages were classified as public (suitable for anybody to view), 25% as semi-public (suitable for a subset of viewers), 15% as private (suitable perhaps only for a close confident), and 18% as don't save (either irrelevant or extremely private). Similar results were found in the second study, conducted in 2005 (Hawkey & Inkpen, 2006a): 40% public, 20% semi-public, 25% private, 15% don't save. It must be noted that participants in both studies exhibited a great deal of individual variability in their privacy classifications with some participants having greater privacy concerns than others. This variability is both as a result of participants having differing privacy concerns for similar content and as a result of them having conducted browsing activities of differing sensitivity.

Studies have found that privacy concerns are highly nuanced and individual (Ackerman, Cranor, & Reagle, 1999; Hawkey & Inkpen, 2006a). Recent information sharing research has investigated privacy concerns for various types of information and recipients of that information. For example, one study investigated privacy comfort for participants when sharing information with a recipient (Olson, Grudin, & Horvitz, 2005). Privacy concerns differed depending on the person's relationship to the receiver of the information as well as on the type of information being shared. Their results suggest that some of the types of information that may be revealed in Web logs, such as personal activities like viewing non-work related websites and transgressions like viewing erotic material, are considered more sensitive than information such as contact and availability information. The amount of control that the individual retains over the disclosure of information may also impact their level of comfort (Palen & Dourish, 2003).

A person's demographics such as age and gender may affect their privacy disposition (Hawkey, 2007). However, a person's disposition to privacy, that is, their inherent privacy concern, is also grounded in their life experience. For example, their technical level or computer experience may impact their inherent privacy concerns. Additionally, dispositional variables may moderate the effect of situational variables. Someone with strong inherent privacy concerns may always be very private, someone with weak concerns may be less private, others may be more pragmatic and may more often modify their privacy comfort and browsing activities in response to the state of the environment (Hawkey, 2007; P&AB, 2003).

While inherent privacy concerns indicate someone's overall privacy preferences, the situational context will determine which information a person feels is appropriate to reveal (Joinson, Paine, Reips, & Buchanan, 2006; Westin, 2003). For example, in a study examining online disclosure of information, independent pathways were found for the dispositional variable of participant's general privacy concerns as well as the situational variables of perceived privacy (in terms of anonymity and confidentiality) and participants' trust in the receiver of the information (Joinson, Paine, Reips, & Buchanan, 2006). Similarly Malhotra et al. (2004) developed a causal model of online consumers' information privacy concerns. Their model considered the effect that Internet users' information privacy concerns have on trusting beliefs, risk beliefs, and their behavioral intention to reveal personal information. Furthermore, they incorporated the sensitivity of the information requested by marketers as a contextual variable and considered covariates such as sex, age, education, Internet experience, identity misrepresentation, past experiences with privacy invasion, and media exposure. They developed measures for new factors of privacy concerns including control (i.e., whether the user has control over the data) and awareness (i.e., whether the user is adequately informed as to use of the data) to augment existing scales for this domain which consider collection of information such as whether the exchange of personal information is equitable.

Privacy comfort for the viewing of Web browsing activity has also been found to depend not only on a person's disposition to privacy, but also on the situational context when the activity is revealed (Hawkey, 2007). Situational variables for privacy concerns associated with traces of activity in Web browsers include the computing device used and the location of use. Furthermore, within each location there may be other variables such as the current role of the user, social norms for the location, rules for personal Web browsing activities, and different types of viewers of the display and users of the device. These variables may constrain or shape both the browsing activities and the subsequent privacy concerns. For example, someone with Web access on both a home and a work computer may refrain from conducting many personal activities while at work, while someone with only access at work may conduct a broader range of activities in the workplace. A laptop user may perform the majority of their browsing activities on their laptop, but their viewing concerns may change as they move between different locations with different social norms. One's browser settings and preventative actions taken may also change depending on the usage environment. Beyond which traces are potentially visible as a result of these changes, the perceived sensitivity of the traces may also change as a result of the viewing situation. The cost and benefit of disclosure depends on the specifics of each situation (Joinson, Paine, Reips, & Buchanan, 2006).

Marx (2003) identified several privacy enhancing methods that people use when under surveillance, with *self-regulating*, *blocking*, *masking*, *switching*, and *refusal* activities being particularly applicable to mitigating privacy concerns associated with Web browsing data. For example, Web browsing activities may be *self-regulated* in the workplace to avoid surveillance by an employer, with more personal activities being conducted solely at home (Hawkey & Inkpen, 2006b). A person's attitudes and perceptions about privacy, trust, and social relationships or norms (e.g., workplace rules) will influence his behavior in a situation (Liu, Marchewka, Lu, & Yu, 2004). A common privacy preserving strategy employed within Web browsers is to *block* the recording of visited sites by turning off the convenience features such as history files and auto complete data (Hawkey, 2007). One downside to this approach is that a complete lack of visited sites within the browser's history files may be viewed as an indicator that there is an activity worth hiding. A more subtle approach would be to *mask* the activity rather than to block it completely (Marx, 2003). For example, to mask browsing activities in their personal bookmarks, users can rename stored sites to conceal the nature of the page (Hawkey, 2007). In order to guard privacy at the server level, users may opt to anonymize their browsing, thereby masking their identity (Cranor, 1999). Internet users in the studies surveyed by Teltzrow and Kobsa (2004) have taken steps such as *refusing* to give personal information to a Website and supplying false information to a Website when asked to register. S*witching* computers or browser applications to avoid logging software is a privacy enhancing mechanism that can impact the breadth of data recorded during studies (Kellar, Hawkey, Inkpen, & Watters, 2008). Finally, *refusing* to take part in studies altogether may also occur if the privacy concerns are too high (Tang, Liu, Muller, Lin, & Drews, 2006).

PRIVACY CHALLENGES ASSOCIATED WITH THE LOGGING OF WEB DATA

Much of the privacy background just presented was focused on the privacy concerns associated with the types of data that may be captured in Web logs. In this section, two facets of privacy challenges associated with Web logging data are discussed. The first are standard privacy concerns with respect to the capture, storage, transfer, and re-use of data. These are largely dictated by governmental and organizational regulations. The second are privacy concerns that participants may have about their activities being recorded. These concerns may affect their natural Web browsing behaviors during the study period and can be challenging to address.

Governmental and Organizational Regulations

The first concern when designing a study with Web log analysis is ensuring that governmental regulations (e.g., PIPEDA in Canada) or organizational regulations, such as a university's Research Ethics Board (REB) policies, with respect to privacy are met. These regulations will specify requirements for data collection including the storage and safeguarding of participant data as well as the use, re-use, and transfer of that data. As these regulations are specific to the country and institution where the research is located, they will not be extensively described here. However, some general areas for consideration will be presented. It is up to individual researchers to ensure that they are in compliance with the policies that govern their research.

Many REB and governmental policies address the period of time that data may be kept and the storage requirements for that data. In addition, data re-use may be limited to the purposes identified in the study materials and agreed to by participants. While it may be tempting to provide very broad potential use cases, more narrow usage possibilities may assuage participant concerns about the capture of what can be potentially sensitive data (Teltzrow & Kobsa, 2004).

Governmental regulations may even dictate which data logging software is used. For example, in Nova Scotia, Canada, the Personal Information International Disclosure Protection Act has recently been approved by the Nova Scotia provincial government (Dalhousie Research Services, 2006). This legislation deals with protection, storage, and management of personal information of Nova Scotians, and the issue of data transfer outside Canada is prominent. Special approval is required to use software, hardware, or services that store personal information of Nova Scotians outside of Canada, and permission must be granted to transfer data containing personal information to researchers outside of Canada.

Governmental regulations will likely apply to the storage and use of the data, although requirements may be lessened if the data is anonymized. Data collection itself may be anonymous (i.e., collected with no associated identifying information) or the data set may be anonymized through removal of any links between the data and identifying information. To be considered anonymized, there must be no way for an investigator to connect the data with a specific participant. This can be difficult with small data sets due to the potential triangulation of the data to a specific individual in the study population. Care must be taken that the data does not include potentially identifying information such as highly detailed demographic information or IP addresses (Dalhousie Research Services, 2006).

Depending on where the log data is captured (i.e., server-side, client-side) and the frequency with which the data needs to be transferred between the participant and the researchers, different security mechanisms are required to safeguard the data and ensure that participants' privacy is not inadvertently compromised. While discussion of security mechanisms is outside the scope of this chapter, there are several resources that may be useful (Garfinkel & Spafford, 2001; Huseby, 2004; Meier et al., 2003). The discussion in this section is limited to the tradeoffs inherent with different approaches.

When possible, researchers should take advantage of opportunities of anonymizing or otherwise transforming the data before receiving it. For example, with client-side storage of data, a data collection script can remove any identifying information such as IP addresses that may be stored in the data logs and assign a random user ID number that is not tied to recruitment or screening data. Furthermore, potentially identifying or sensitive information can be transformed into higher level data. For example, if a study would like to record where laptop users accessed the internet, a data collection script could take as input IP addresses and location labels and replace the personally identifying IP addresses in the data records with a general location field (whether home, work, or school) (Hawkey, 2007).

One question that arises during research that makes use of Web logs is where to store the data, and when and how to transfer the data between participant and researcher (Kellar, Hawkey, Inkpen, & Watters, 2008). When data is logged during a laboratory experiment, or with proxy or server-side logging applications, it is typically stored directly on a research computer. With proxy logging, researchers should provide a secure connection to the proxy server. Additional complexities arise for client-side data logging as data transfer and storage issues must be determined. Storing the data locally on the participant's machine for the duration of the study (and removing it physically during an uninstall session) may simplify the participants' duties and minimize privacy risks associated with the transfer of data; however, researchers run the risk of data loss if the participant's machine crashes. If data is transferred more frequently, the participant may be inconvenienced and there is a need to provide secure methods of transmission.

Impact of Privacy Concerns for Data Collection on Natural Web Browsing Behaviors

The remainder of this chapter will deal with the impact of privacy concerns on the ability of studies to capture natural Web browsing behaviors. It is important to consider that the act of recording visited sites may impact participants' normal Web browsing activity (McGrath, 1995). As previously discussed, there are privacy concerns associated with others viewing visited websites (Hawkey & Inkpen, 2006b; Olson, Grudin, & Horvitz, 2005; Teltzrow & Kobsa, 2004). Self-regulation of activity is one mechanism used to preserve privacy when under surveillance (Marx, 2003). However, for most studies involving the logging of Web data, it is important that participants conduct their Web-related activities as they normally would, regardless of the social desirability of the content (Fisher, 1993) or the personal information that may be captured.

Which traces of prior activity may be disclosed depend on the type of data logging being done. There are several challenges and tradeoffs when trying to capture rich contextual data (Kellar, Hawkey, Inkpen, & Watters, 2008). One key factor in determining an appropriate data logging strategy is the tradeoff between the amount of control the researcher retains and the amount of intrusiveness for the participant (McGrath, 1995). This chapter considers this tradeoff, extending the discussion of the impact on privacy concerns and the ability to capture natural Web browsing behavior for various Web logging strategies.

One approach is to use trace measures or archival records (McGrath, 1995). Archival records are records of user behavior that are collected for other purposes and may either be private or public knowledge. Examples of archival records include blogs or stored bookmarks in the Web browser. Trace measures are records of behavior inadvertently left by participants, such as Web server data logs created through server-side logging. If data is gathered after the fact, there will be no behavioral changes due to observation. However, there are several drawbacks to this approach, and the available data may not be appropriate depending on the research questions of interest.

Cockburn and McKenzie (2001) used archival data to conduct an empirical analysis of Web page revisitation. They analyzed the history records from academic user accounts captured on server backups. History records are stored within a Web browser to enable revisitation of previously visited sites. An advantage to their approach was that there were no behavioral changes due to observation as the participants were unaware at the time of web browsing that their browsing activities would be examined as part of a study. However, the data available was not complete. The history files only included the most recent timestamp for accessing a URL, so some visits were not captured temporally. Data collected in this fashion is generally limited in contextual information about the activities underway. Additionally, it may be difficult to get permission to use archival data if the participant is unclear about which sensitive activities may have been conducted during the study period.

The use of trace measures such as server logs will similarly remove behavioral changes due to observation. However, server-side logging generally limits the breadth of the data collected, either capturing only the access to a single website or access through a specific Web portal (Yun, Ford, Hawkins, Pingree, & McTavish, 2006). The data is also usually limited to the IP address of users, a time stamp, and the URL requested. Web server logs may be incomplete records of an activity, since page requests may not be received and recorded at the server if the page has been cached by the browser or a proxy server (Fenstermacher & Ginsburg, 2003). There is ongoing tension between Web users' privacy needs and a website's requirement for information about its users (Cooley, Mobasher, & Srivastava, 1999). While the use of cookies can alleviate problems of identifying returning individuals that are associated with dynamic IP addresses (Anick, 2003), users may turn off cookies in order to protect their privacy (Teltzrow & Kobsa, 2004). Users may also attempt to enforce privacy through obscurity, controlling release of personal information by using an anonymization service such as a proxy server (Sackmann, Struker, & Accorsi, 2006). A proxy server may assign many users to the same IP address and can make user identification difficult.

Observations consist of records of behavior intentionally collected by a researcher or their software; observations may or may not be visible to the participant (McGrath, 1995). For example, a researcher watching a person interacting with an application would be visible to the participant, while the application logs capturing user interactions would not. One of the main concerns with observational data is that natural behaviors will often be adjusted if the participant is aware of the observations. Software that captures observational data can be proxy-based or client-side.

If Web activity is captured through proxy logging, the user must login at the beginning of each session. Advantages to this approach are that it is easier to capture data across websites, and there are fewer participant identification issues than with server-side logging due to the use of a participant account. However, users may bypass the proxy server if concerned about the sensitivity of their browsing or if they are forgetful. This may limit the breadth of data collected. Another advantage to proxy logging is that participants can work within their normal Web browser environment. However, with traditional proxy logging, browser interactions cannot be captured; and there are still caching issues if pages are cached at the browser level (Barford, Bestavros, Bradley, & Crovella, 1999). One emerging method of data logging is to embed Javascript into delivered web pages through the proxy server (Atterer, Wnuk, & Schmidt, 2006). This method can be used to capture additional data including mouse movement, scroll bar use, and key presses. Proxy servers have also been found to be less reliable and accurate than client-side logging tools for temporal measurements of Web activity (Kelly & Belkin, 2004).

One advantage of field research over laboratory experiments is that participants have access to their usual Web tools, browsers, and physical environments (Kellar, Hawkey, Inkpen, & Watters, 2008). However, with client-side logging, there is a danger of altering the participants' Web browsing environment when attempting to capture natural Web browsing behavior that is also rich in detail. The Web browsing environment includes many factors such as the user's physical location and their usual browser application, including all its normal settings. One of the main reasons for selecting field studies as a methodology is to capture natural user behavior which can be important for studies which are investigating patterns of activity. It is therefore important that the experimental software not interrupt the flow of participants' Web browsing (Chatterjee, Hoffman, & Novak, 2003).

The choice of a client-side logging tool can help mitigate concerns about changing the Web browsing environment of the user. For example, a browser helper object (BHO) can be ideal for this purpose as participants can continue using Internet Explorer with their normal settings intact, including their Favorites, History, and Google toolbar (Kellar, Hawkey, Inkpen, & Watters, 2008). The automatic loading of the BHO means that participants do not have to remember to use the study instrument. However, a BHO can only record limited types of data (i.e., interactions at the Web document level). In order to record richer interactions with the Web browser itself, a custom Web browser must be used. Developing a custom Web browser that fully mimics the appearance and functionality of participants' commercial browser applications, including all installed features (e.g., user-installed toolbars) is challenging. In some instances, researchers may have access to the source code of a commercial browser. Adapting open source software (e.g., Mozilla Firefox) is a popular choice for researchers wanting to augment browser functionality to include logging (Weinreich, Obendorf, Herder, & Mayer, 2006); however, this can limit the user population or result in participants using a different Web browsing environment as the most common browser in use is still Internet Explorer.

There are additional privacy challenges if trying to capture participants' Web activities across all contexts of use with client-side logging. It can be difficult to install the software on all computers and devices in use, particularly if custom logging software is not robust and well-tested (Kellar, Hawkey, Inkpen, & Watters, 2008). If a computer in use is not owned by the participant (i.e., one located in the workplace), it may be difficult to receive corporate permission to record data (Tang, Liu, Muller, Lin, & Drews, 2006). Self-regulation of browsing activities that are not work-related may occur if the participant believes there is a chance that the employer may have access to the logs or be able to discern their identity in subsequent analysis. In such a case, it is very important to provide privacy preserving mechanisms to help alleviate concerns of both the participant and the employer.

As summarized in Table 1, while server-side logging has relatively few privacy concerns due to the difficulty of linking the data to specific users and their personal information, it suffers from a reduced amount of information that can be gathered. Data is primarily limited to navigation with a website and data entered at that site; it will not include navigation to cached pages or websites located on other servers. Client-side logging can provide richer data, but the data collection is more invasive from a privacy perspective. As the software must be installed on client computers, the participants (and their personal information) are usually known to the researchers. Depending on the logging software, a great deal more information may be logged, including interactions with the Web browser and key strokes. Proxy logging, particularly if making use of Javascript to capture some of the user interactions, may be

Table 1. Summary of tradeoffs by type of logging for richness of data, completeness of data, ability to discern individual participants, and naturalness of their Web browsing environment.

	Server-side Logging	Proxy Logging	Client-side Logging
Richness of data	Limited to navigation, data entry on site	Limited to navigation, some form data, - improved with scripting	Rich data including navigation, key strokes, browser interaction, but BHO more limited
Completeness of data	Caching issues, site specific	Caching issues, can be bypassed	Can be bypassed by using other browser or other computer
Ability to discern individual users participants	Can be difficult (anonymization services)	Good (must log in)	Good
Naturalness of participants' browsing environment	Completely natural	Participants aware of the logging /but browser environment unchanged	Participants aware at install. Environment depends on software (BHO generally transparent, but custom browsers may not have usual functionality and settings)

a viable compromise depending on the research objectives.

ENHANCING PRIVACY DURING OBSERVATIONAL DATA COLLECTION

Collection of observational data, particularly through client-side logging applications can provide researchers with rich data about Web browsing activities and behaviors, including interactions with the Web browser. However, the intrusiveness of this type of data collection may cause participants to alter their natural Web browsing behaviors, avoid using study software, or refuse to take part in the study altogether. It is important for researchers to provide mechanisms for participants to preserve their privacy. Recommendations for such privacy enhancing mechanisms are presented next.

Lederer et al. (2004) discuss how users should be able to maintain personal privacy through understanding and action. Understanding is required so that users are aware of potential privacy violations. Opportunities for action are required so that users can appropriately manage their privacy when necessary. Following this lead, the recommendations for providing privacy preserving mechanism in this chapter will be presented with two thrusts. The first is to increase participants' understanding of the data logging and its privacy implications and to also increase their trust in the researchers' ability to maintain their privacy. In addition to educating participants, trust can be increased by limiting the recorded data to that necessary to answer the research questions and providing opportunities for participants to inspect the recorded data. Second, recommendations will be given for privacy-enhancing actions that may be afforded to participants building on the methods identified by Marx (2003) for maintaining privacy in case of surveillance. These actions include the ability to pause recording as well as the ability to mask or delete sensitive records.

Recommendations for Increasing Understanding and Trust

Lederer et al. (2004) make the point that unless users can readily determine the nature and extent of potential information disclosure, they will not be able to fully understand the privacy implications as a result of system use. For participants to be comfortable enough with the logging software to engage in their usual Web browsing activities, it is important that they understand the data being captured. The issue of trust is also an important facet of privacy concerns. Internet users' willingness to share information with a website may depend on their level of trust towards the owner of the website (Teltzrow & Kobsa, 2004).

Recommendation 1: Educate Participants

The Platform for Privacy Preferences (P3P) Initiative provides mechanisms for Web users to understand the privacy policies of websites with which they interact. Privacy in this sense is based on transparency through policies; users can inspect an organization's privacy policies and must rely on their trust in an organization to follow the stated polices (Sackmann, Struker, & Accorsi, 2006). Similarly, transparency in the process can be used to educate participants in studies involving data logging.

Consent forms should explicitly describe data collection and use so that participants have a clear understanding of what data will be collected, who will be able to see it, how the data will be used, and how it will be reported. By explicitly providing this information to participants, as well as detailing any privacy preserving mechanisms in place, researchers should be able to assuage any general privacy concerns that may prevent potential participants from taking part in the study as well as address potential privacy violations specifically. Interestingly, participants may not always take advantage of the privacy preserving mechanisms provided (Kellar, Hawkey, Inkpen, & Watters, 2008); however, the very existence of these mechanisms can give potential participants a sense of control over the privacy of their Web browsing activities which may encourage them to take part in an intrusive field study (Obendorf, personal communication, January 2008).

Recommendation 2: Only Record / Receive as Much Information as Needed

In the E-Commerce domain, it is suggested that websites gathering personal information for the purposes of personalization only gather that information that is required for the immediate service (Teltzrow & Kobsa, 2004). Limiting data collection can also increase users' willingness to disclose the information. A similar policy should help with data logging for research purposes. While it is tempting to gather as much information as possible, privacy concerns may be minimized by only recording that data which is necessary to answer the research questions. By limiting the data collected (and providing details to participants about how it will be used), participants should feel more secure that their data is being respected and being used to further research in the area of interest.

Furthermore, there may be times when very detailed raw data will be collected, but the measures of interest are aggregate scores or temporal patterns. In such cases, it may be possible to collect and process the data on the client's machine, only receiving the processed data (Hawkey, 2007). For example, if the data of interest is revisitation patterns, the URL may be necessary to identify unique pages, but otherwise irrelevant to the research questions. A script could process the data, assigning a unique ID to each URL. This would preserve the data necessary for calculations while obscuring the actual sites visited which should alleviate privacy concerns. One disadvantage to this approach is that the researcher must be well-prepared and be sure of all data analysis that will be required.

Hawkey and Inkpen (2005) were interested in investigating overall privacy concerns and temporal privacy patterns associated with the later viewing of visited Web pages. The page title and URL of visited pages were collected in order to allow participants to annotate their browsing with a privacy level in an electronic diary. In order to provide participants with as much privacy as possible, the page title and URL were stripped from the records after annotation, so that only a browser window ID, date/time stamp, and privacy level were sent to the researchers. These data were sufficient to investigate the preliminary research questions, and it was hoped that this reduction in information would encourage participants to engage in their regular Web browsing activities regardless of the sensitivity of visited pages. After an informal survey of privacy concerns associated with their longitudinal field study of Web browsing behavior, Weinreich, Obendorf, Herder & Mayer (2006) opted to use a capturing system that did not record user names and passwords entered in the browser and that ignored activity on secure connections.

Recommendation 3: Provide Opportunities for Inspection of Data

Recent research discussions have suggested providing evidence creation as a way to increase transparency and allow auditing of the data collected (Sackmann, Struker, & Accorsi, 2006). Privacy evidence is created by interpreting the collected logged data about an individual through the lens of the policies applicable to that data to illustrate compliance. Providing opportunities for participants to inspect the data being sent to researchers is a method of increasing this transparency and reassuring them that only the agreed upon data is being transferred.

This was a technique used by Hawkey and Inkpen (2005; 2006a). After using an electronic diary to annotate their visited Web pages with a privacy level, participants generated a report to email to the researchers. This report allowed participants to inspect (but not change) the data, which served as confirmation of precisely which aspects of their Web browsing activity were being transferred to the researchers. Weinreich et al. (2006) also took this approach, allowing participants to view their logged data prior to transmitting it to researchers; as discussed later, they did allow participants to take actions on that data.

Affording Privacy Preservation through Action

Three of Lederer et al.'s (2004) pitfalls relate to privacy preserving actions. The authors state that users should not have to extensively configure a system a priori in order to maintain privacy, but rather should be able to manage privacy within their normal interaction with the system. Additionally, their normal interaction with the system should not be hampered by the actions they must take to preserve privacy, nor should their normal mechanisms of preserving privacy, such as taking advantage of plausible deniability, be hampered by the technology. Furthermore, users should be able to quickly stop the release of information (i.e., have mechanisms of coarse-grained control) so that they can respond to unanticipated or quickly changing situations of use. One difficulty with providing real-time privacy enhancing mechanisms for participants is that this feedback may impact the natural flow of their Web browsing activities and make them more conscious of being observed.

The amount of control a person has over what information is recorded in Web data logs must be balanced with the need for that data for the research purposes. While not all of these recommendations may be appropriate for a given study, providing participants with some level of control over their data should help alleviate privacy concerns (Teltzrow & Kobsa, 2004). The intent of these recommendations is to provide participants with similar privacy-preserving mechanisms to those that they might use in their normal Web interactions when trying to limit the data collected by Web-servers (Cranor, 1999) or when under surveillance (Marx, 2003).

Recommendation 4: Provide the Ability to Pause Recording

Client-side logging software can be developed to automatically log all Web browsing actions or to be manually started by participants on a periodic basis. As previously stated, browser helper objects automatically load when Internet Explorer is loaded; a similar method is the Cross Platform Component Object Model (XPCOM) for Mozilla's Firefox browser. Participants may still bypass the collection of data, however, by using a different Web browser. Custom Web browsers generally must be manually started by the participant. This provides participants with an opportunity to only log those browsing activities that they wish to share. This may be suitable for research investigating episodes of targeted activity such as information seeking tasks as in Kellar et al. (2007). In that case, participants were asked to use a custom web browser periodically to perform information seeking tasks. Their participants could opt not to use the custom browser when conducting sensitive browsing activities.

If periodic recording of data is suitable for the research question, custom logging software such as Web browsers or toolbars associated with browser helper objects or other browser plug-ins should include a recording button that can be toggled on and off. This will allow participants to pause recording of their browsing when engaging in sensitive activities such as visiting socially inappropriate websites or engaging in confidential transactions. This can be very important when recording keystroke data that may include passwords. Alternatively, data logging software could be developed to avoid collecting password data or form field data if this data is not pertinent to the research question (Weinreich, Obendorf, Herder, & Mayer, 2006).

Recommendation 5: Provide the Ability for Participants to Mask Data

Another way to provide privacy for participants is to allow them to mask sensitive data. This may be more appropriate for studies which would like to capture all of a participant's browsing activities. Depending on the research questions, one or more fields in a data log may be candidates for masking.

Kellar et al. (2007) used masking in their field study investigating information seeking tasks and their impact on the use of Web browser navigation mechanisms. Participants could remove details about specific visited pages deemed to be sensitive. Masking was also an approach taken by Hawkey and Inkpen (2006a) in a field study investigating participants' visual privacy concerns for traces of their Web browsing activity. In this study, the researchers wanted to investigate the impact of context (location, visited page) on privacy concerns. They therefore needed to not only collect the URL and page title for annotation by participants within the electronic diary (as in their 2005 study), but to also receive that information as part of the generated report. As they did not want receipt of this additional information to impact participants' willingness to visit sensitive sites, they provided participants with the ability to selectively blind any sensitive data contained in the URL and page title. The electronic diary in Hawkey and Inkpen's (2005) study was modified to allow participants to mask entries in the diary by removing the page title and URL after applying a privacy level to a visited web page. When masking an entry, participants were asked to give a general reason for the sanitized browsing such as "looking for medical information"; the default label was "no reason given." An inspection of the visited pages revealed that the proportion of participants in the field study with instances of adult content was comparable to frequency reports of erotica viewing as reported by participants in a related anonymous survey (Hawkey & Inkpen, 2006b).

This may indicate that participants' normal Web usage, including those activities not considered to be socially desirable (Fisher, 1993), was recorded during the study.

Recommendation 6: Provide Participants with the Ability to Delete Data

Deletion of records may be feasible for some research questions. Deletion is similar to pausing of the recording but is done after the fact. Research questions that may be answered by investigating specific episodes of Web browsing would be candidates for this approach. In order to preserve the integrity of the data, researchers may want to limit how the data can be handled, perhaps providing a data viewer that allows deletion at the record level, but no modifications of individual fields. Alternatively, deletion could be offered at the session level by providing participants with the opportunity to consent to the session being included in the study data upon exiting the data collection software. Weinreich, Obendorf, Herder & Mayer (2006) allowed their participants to view the data logs (as text files) before transmitting them to researchers. The text files were editable, so participants could potentially modify the data at will, either through masking or deletion of specific records or entire files; however, no participants are believed to have actually modified their data (Obendorf, personal communication, January 2008).

FUTURE TRENDS

The previous sections presented current challenges for researchers attempting to capture observational data and provided several recommendations for enhancing participant privacy in an effort to encourage users to engage in their normal Web browsing behaviors (summarized in Table 2). Privacy concerns of participants can be expected to increase as researchers gather more contextual information during studies, including their users' activities, goals, attitudes, and processes, to augment logged data (Kellar, Hawkey, Inkpen, & Watters, 2008). Contextual information plays an important role in how we understand and interpret people's everyday behavior. Information that provides additional details about people, such as their location or task, can help us better understand and interpret their actions. In a Web environment, contextual information can be used to determine the activities in which a user is engaging, their motivations for engaging in those activities, as well as perceptions about the current tool or the information being viewed. Participant annotation of log data is one emerging method of gaining additional context (Kellar, Hawkey, Inkpen, & Watters, 2008). Another method is to retrospectively discuss portions of the data logs with participants using critical incident techniques (Choo, Detlor, & Turnbull, 2000).

There is also an increasing need to capture Web activity across usage contexts. It is important during studies of natural browsing behaviors that we record specific aspects of context that may be influencing behaviors at the time and capture those behaviors across all normal usage contexts. Web usage can vary across different locations (e.g., home, work) and devices (laptop, desktop) (Hawkey, 2007). Additionally, different Web browsers or Web browser settings may be used in these environments, and browsing may be conducted for different purposes (e.g., personal, work-related). There will be many research challenges to ensure that participant privacy is considered across contexts of use, as well as the privacy of any companies or organizations involved. As the boundaries between personal time and work time decrease, more and more participants may be multi-tasking across contexts (Olson-Buchanan & Boswell, 2006).

Loggers that capture data across applications are becoming more common as researchers investigate behaviors at the level of the activity or

Table 2. Summary of recommendations for enhancing participants' privacy and thereby encouraging natural Web browsing behaviors.

Recommendations for Enhancing Privacy when Logging Web Browsing Activity
Increase Privacy and Trust
1. Educate participants about what information is being collected
2. Only record/receive as much information as is needed for the research questions
3. Provide opportunities for participants to inspect the data collected
Afford Privacy Preservation Through Action
4. Provide the ability for participants to pause recording of the data
5. Provide the ability for participants to mask particularly sensitive data
6. Provide participants with the ability to delete data

are gathering more contextual information about multi-tasking. Such logging applications increase privacy concerns of participants, whether they are keystroke loggers or screen capture applications. Screen capture software gives context by revealing what the user sees while interacting with their Web browser including applications outside of the Web browser. If such applications are used, participants are essentially agreeing to have all of their computer activity logged. It can be very difficult to recruit users to take part in such studies, and there may be privacy concerns not only for the participants, but for those with whom they communicate (i.e., email correspondence) (Tang, Liu, Muller, Lin, & Drews, 2006). Research ethics boards may require informed consent from all collaborators before their data is recorded.

As more contextual data is captured and more logging is conducted across applications, it will be increasingly important for researchers to consider participants' privacy concerns (Kellar, Hawkey, Inkpen, & Watters, 2008). Providing privacy enhancing methods such as those suggested in the recommendations should help alleviate privacy concerns which may impact recruitment efforts and encourage participants to engage in their usual activities. Researchers will need to be innovative in their methodological techniques as they balance the participants' desires for privacy with researchers' need for rich data to answer questions of interest.

Researchers must also keep abreast of changing privacy regulations at the governmental and organizational level. Given current political climates, it is expected that more rigid protections of data and their re-use will be legislated. Keeping informed of current practices is particularly important if conducting research across borders, as regulations vary widely.

CONCLUSION

This chapter first presented relevant privacy literature including general privacy theories and privacy concerns specific to Web browsing activities. This background provided the necessary grounding for the subsequent discussions of privacy issues with respect to the collection of log data for analysis. The main privacy issues presented were 1) ensuring that governmental and organizational regulations with respect to the safeguarding of participant data are met and 2) providing privacy preserving mechanisms for participants in order to encourage natural Web browsing behaviors. Privacy concerns will depend on the type of data logging. Several tradeoffs were discussed according to the location of the data logging (see Table 1 for a summary). While server-side data is less intrusive for participants and allows them to engage in their normal privacy preserving mechanisms, the data collected is limited and often unreliable. Client-side logging can provide richer data including Web browser interactions; however, data collection is more intrusive.

Several key recommendations for mechanisms to enhance participants' privacy were suggested (see Table 2 for a summary). These include ways to increase participants' understanding and trust of the data logging for the study as well as methods to allow them to control the capture of particularly sensitive data through masking, blocking, or deleting it. The author hopes that these recommendations will prove to be useful for researchers designing research methodologies that include the capture of observational data.

KEY TERMS AND DEFINITIONS

Anonymized Data: Data that has been collected with identifying information, but has had subsequent removal of any links between the data and identifying information so that the researcher can no longer discern the specific owner of the data.

Anonymous Data: Data that is collected without any associated identifying information.

Client-Side Logging: Software that records Web browsing behavior at the user's computer. This is generally achieved either through a custom web browser or through browser plug-ins such as tool bars or browser helper objects.

Contextual Privacy Concerns: Privacy concerns vary in any given instance according to the inherent privacy concerns of the user and the situational factors at play. These include the viewer of the information, level of control retained over the information, and the type of information. Furthermore, these factors can vary according to the device in use and the location.

Inherent Privacy Concerns: An individual's general privacy concerns; their disposition to privacy. Factors which may impact a person's disposition to privacy include their age and computer experience.

Privacy: "The claim of an individual to determine what information about himself or herself should be known to others." (Westin, 2003).

Proxy Logging: Software that serves as an intermediary between the user's web browser and the web site servers. Users generally have to log-in to the proxy and the proxy server can be used to augment retrieved web pages.

Server-Side Logging: Software that records Web browsing behavior at the server. Data collection is generally limited to navigation information.

Web Browsing Behaviors: User behaviors on the Web including their browsing activities and Web browser interactions. Privacy concerns have been found to impact Web browsing behaviours.

Web Browsing Environment: The context within which Web browsing occurs. For studies of Web usage this includes the Web browser and its associated tools (e.g., history, specialized toolbars), the task, and the motivation for conducting the browsing.

ABSTRACT

Web service orchestration languages are defined to describe business processes composed of Web services. A business process can fail for many reasons, such as faulty Web services or mismatching messages. It is important to find out which Web services are responsible for a failed business process because we could penalize these Web services and exclude them from the business process in the future. In this paper, we propose a model-based approach to diagnose the faults in a Web service-composed business process. We convert a Web service orchestration language, BPEL4WS, into synchronized automata, so that we have a formal description of the topology and variable dependency of the business process. After an exception is thrown, the diagnoser can calculate the business process execution trajectory based on the formal model and the observed evolution of the business process. The faulty Web services are deduced from the variable dependency on the execution trajectory.

INTRODUCTION

Web services not only function as middleware for application invocation and integration, but also function as a modeling and management tool for business processes. In a Service Oriented Architecture paradigm, a business process can be composed of Web services distributed over the Internet. This kind of business processes can be flexible and optimal by using the best services from multiple companies. Various Web service process description languages are designed by standard bodies and companies. Among them, Business Process Execution Language for Web Service (BPEL4WS, denoted as BPEL after) (Andrews, Curbera, Dholakia, Goland, el al., 2003) is the de facto standard used to describe an executable Web service process. In this article, we study the behavior of a business process described in BPEL.

As any other systems, a business process can fail. For a Web service process, the symptom of a failure is that exceptions are thrown and the process halts. As the process is composed of multiple Web services, it is important to find out which Web services are responsible for the failure. If we could diagnose the faulty Web services, we could penalize these Web services and exclude them from the business process in the future. The current throw-and-catch mechanism is very preliminary for diagnosing faults. It relies on the developer associating the faults with exceptions at design time. When an exception is thrown, we say certain faults occur. But this mechanism does not guarantee the soundness and the completeness of diagnosis.

In this article, we propose a model-based approach to diagnose faults in Web service processes. We convert the basic BPEL activities and constructs into synchronized automata whose *states* are presented by the values of the *variables.* The process changes from one state to another by executing an *action*, for example, assigning variables, receiving or emitting messages in BPEL. The emitting messages can be a triggering *event* for another service to take an action. The diagnosing mechanism is triggered when exceptions are thrown. Using the formal model and the runtime observations from the execution of the process, we can reconstruct the unobservable trajectories of the Web service process. Then the faulty Web services are deduced based on the variable dependency on the trajectories. Studying the fault diagnosis in Web service processes serves the ultimate goal of building self-manageable and self-healing business processes.

This article is organized as follows: the Advanced Fault Management for Web Service Processes section analyzes the fault management tasks in Web service processes and motivates the use of Model-based Diagnosis (MBD) for Web services monitoring and diagnosis; The Principle of Model-based Diagnosis for Discrete Event Systems section presents the principles for MBD; the Modeling Web Service Processes with Discrete-Event Systems section formally defines the way to generate an automaton model from a BPEL description; the Model-based Diagnosis for Web Service Processes section extends the existing MBD techniques for Web service monitoring and diagnosis; the Related Work and Discussion section is the related work, and lastly is the Conclusion section.

ADVANCED FAULT MANAGEMENT FOR WEB SERVICE PROCESSES

A Web service process can run down for many reasons. For example, a composed Web service may be faulty, an incoming message mismatches the interface, or the Internet is down. The *symptom*[1] of a failed Web service process is that *exceptions* are thrown and the process is halted. The current fault handling mechanism is throw-and-catch, similar to programming languages. The *exceptions* are thrown at the places where the process cannot be executed. The *catch* clauses process the exceptions, normally to recover the failure effects by executing predefined actions.

The throw-and-catch mechanism is very preliminary for fault diagnosis. The exception reports where it happened and returns some fault information. The exceptions can be regarded as associated with certain faults. When an exception is thrown, we deduce that its associated fault occurred. Customized exceptions are especially defined for this purpose. This kind of association relations rely on the empirical knowledge of the developer. It may not be a real cause of the exceptions. In addition, there may exist multiple causes of an exception which are unknown to the developer. Therefore, the current throw-and-catch mechanism does not provide sound and complete diagnosis. For example, when a Web service throws an exception about a value in a customer order, not only the one that throws the exception may be faulty, but the one that generates these data may also be faulty. But a Web service exception can only report the Web service where the exception happens with no way to know who generated these data. In addition, all the services that modified the data should be also suspected. Not all of this kind of reasoning is included in the current fault handling mechanism. *A systematic diagnosis mechanism which is based on the model of the Web service process and a solid theoretical foundation needs to be developed.* This is the objective of this article.

The diagnosis task is to determine the Web services responsible for the exceptions. These Web services will be diagnosed faulty. During the execution of a BPEL process, the exceptions come from the BPEL engine or the infrastructure below, for example. Apache Tomcat, and Internet. We classify the exceptions into ***time-out*** exceptions and ***business logic*** exceptions.

The *time-out* exceptions are due to either a disrupted network or unavailable Web services. If there is a lack of response, we cannot distinguish whether the fault is in the network or at the remote Web service, except if information is transmitted by the network fault management in the first case. Since we cannot diagnose which kind of faults prevent a Web service from responding, we can do little with *time-o*ut exceptions. Indeed what can be done is more statistics at the level of process classes (and not process instances) that will be used by experts to improve the QoS.

The *business logic* exceptions occur while invoking an external Web service and executing BPEL internal activities. For example, mismatching messages (including the type of parameters and the number of parameters mismatching) cause the exceptions to be thrown when the parameters are passed to the remote method. BPEL can throw exceptions indicating the input data is wrong. During execution, the remote service may stop if it cannot process the request. The most common scenarios are the invalid format of the parameters, for example, the data is not in a valid format, and the data is out of the range. The causes of the exceptions are various and cannot be enumerated. The common thread is that a business logic exception brings back information on the variables that cause the problem. In this article, our major effort is on diagnosing business logic-related exceptions at the process instances level.

The advanced fault management mechanism serves the ultimate goal to build self-manageable Web service processes. Fault management mechanisms can be among other self-manageable functions. Some functions related to fault management are:

- **Monitoring** the execution of Web service process, and record necessary and sufficient information for online/offline diagnosis. Insufficient information cannot produce correct diagnosis. In Web service processes, we need to keep a chronological record for some of the variables.
- **Detecting** faulty behavior. In other physical tasks, detecting needs to compare the observations with the predictions from the system description to discover the discrepancies. For Web service processes, this task is a trivial one to observe exceptions. But we can imagine building new detectors in order

to detect symptoms earlier and "closer" to the causes.

- **Diagnosing** the causes of exceptions. This is the major focus of this article. See Model-based Diagnosis for Web Service Processes section for detail.
- **Recovering** from the failure effects. BPEL uses predefined compensation handlers and fault handlers to eliminate failure effects. As failure effects cannot be revealed by the empirical diagnosis mechanism in BPEL, the predefined compensation actions may not be sufficient. A more advanced recovery mechanism has to be defined, based on the model-based diagnosis developed in this article, although it is not covered in this article.

THE PRINCIPLE OF MODEL-BASED DIAGNOSIS FOR DISCRETE EVENT SYSTEMS

MBD is used to monitor and diagnose both static and dynamic systems. It is an active topic in both Artificial Intelligence (AI) and Control Theory communities. Automated diagnosis has been applied to all kinds of systems, such as communication systems, plant processes and automobiles. The early results in MBD are collected in (Hamscher, Console, & de Kleer, 1992). Let us briefly recall the terminology and notations adopted by the model-based reasoning community.

- *SD*: system description. In the AI-rooted diagnostic techniques, SD is symbolically modeled, for example, in first-order logic sentences, and in DES as used in this article.
- *COMPS*: a finite set of constants to represent the components in a system.
- *System*: a pair (*SD*, *COMPS*).
- *D*: a mode assignment to each component in the system. An assignment to a component is a unary predicate. For example, for a component $c_i \in COMPS$, $\neg ab(c_i)$ means c_i working properly, and $ab(c_i)$ means c_i is in an abnormal mode. Obviously a component has different behavior for different modes.
- *Observables*: the variables that can be observed/measured. For a physical system, the observables are the variables measured by sensors, or events reported by alarms, and so forth.
- *OBS*: a set of observations. They are the values of the *Observables*. They can be a finite set of first-order sentences, for example, value assignments to some variables.
- *Observed system*: (*SD*, *COMPS*, *OBS*).

Diagnosis is a procedure to determine which components are correct and which components are faulty in order to be consistent with the observations and the system description. Therefore, logically, a consistency-based diagnosis is:

Definition 1 *D is a consistency-based* ***diagnosis*** *for the observed system* $\langle SD, COMPS, OBS\rangle$, *if and only if it is a mode assignment and* $SD \cup D \cup OBS \not\models \perp$.

From Definition 1, diagnosis is a mode assignment *D* that makes the union of *SD*, *D* and *OBS* logically consistent. *D* can be partitioned into two parts:

- D_{ok} which is the set of components which are assigned to the $\neg ab$ mode;
- D_f which is the set of components which are assigned to the *ab* mode.

Usually we are interested in those diagnoses which involve a minimal set of faults, that is, the diagnoses for which D_f is minimal for set inclusion.

Definition 2 *A diagnosis D is* ***minimal*** *if and only if there is no other diagnosis D' for* $\langle SD, COMPS, OBS\rangle$ *such that* $D_f' \subset D_f$.

The dual concept of a diagnosis is a conflict.

Definition 3 *A set $CO \subseteq COMPS$ is a conflict for $\langle SD, COMPS, OBS\rangle$, if and only if $SD \cup OBS \cup \{\neg ab(C) | C \in CO\} \models \bot$.*

Similarly a minimal conflict is a conflict that is minimal for set inclusion. In (Reiter, 1987), Reiter introduces the hitting set algorithm for computing minimal diagnoses using the set of conflicts.

Definition 4 *((Reiter, 1987)) Let C be a collection of sets. A hitting set for C is a set $H \subseteq \bigcup_{S \in C} S$ such that $H \cap S \neq \emptyset$ for each $S \in C$. A hitting set is minimal if no proper subset of it is a hitting set.*

Theorem 1 *((Reiter, 1987)) A set $D \subseteq COMPS$ is a minimal diagnosis for $\langle SD, COMPS, OBS\rangle$ if and only if D is a minimal hitting set for the collection of conflicts (or equivalently for the collection of minimal conflicts).*

When the system description is in first order logic, the computation of all diagnoses is more generally rooted in automated reasoning, relying on prime implicates of $SD \cup OBS$ in the form of disjuncts of *ab*-literals, and on their prime implicants in the form of conjuncts of *ab*-literals (Hamscher et al., 1992).

When applying MBD, a formal system description is needed. Therefore, we need to study the proper formal model for Web service processes. As the interactions between Web services are driven by message passing, and message passing can be seen as discrete events, we consider the Discrete Event Systems (DES) suitable to model Web service processes. Many discrete event models, such as Petri nets, process algebras and automata, can be used for Web service process modeling. These models were invented for different purposes, but now they share many common techniques, such as symbolic representation (in addition to graph representation in some models) and similar symbolic operations. In this article, we present a method to represent Web service processes described in BPEL as automata in the Modeling Web Service Processes with Discrete-Event Systems section. Here we introduce MBD techniques for automata. A classic definition of deterministic automaton is as follows:

Definition 5 *An **automaton** Γ is a tuple $\Gamma = \langle X, \Sigma, T, I, F\rangle$ where:*

- X is a finite set of states;
- *Σ is a finite set of events;*
- *$T \subseteq X \times \Sigma \rightarrow X$ is a finite set of transitions;*
- *$I \subseteq X$ is a finite set of initial states;*
- *$F \subseteq X$ is a finite set of final states.*

Definitions 6, 7 and 8 are some basic concepts and operations about automata.

Definition 6 ***Synchronization** between two automata $\Gamma_1 = \langle X_1, \Sigma_1, T_1, I_1, F_1\rangle$ and $\Gamma_2 = \langle X_2, \Sigma_2, T_2, I_2, F_2\rangle$, with $\Sigma_1 \cap \Sigma_2 \neq \emptyset$, produces an automaton $\Gamma = \Gamma_1 \| \Gamma_2$, where $\Gamma = \langle X_1 \times X_2, \Sigma_1 \cup \Sigma_2, T, I_1 \times I_2, F_1 \times F_2\rangle$, with:*

$T((x_1, x_2), e) = (T_1(x_1, e), T_2(x_2, e))$, if $e \in \Sigma_1 \cap \Sigma_2$,

$T((x_1, x_2), e) = (T_1(x_1, e), x_2)$, if $e \in \Sigma_1 \backslash \Sigma_2$

$T((x_1, x_2), e) = (x_1, T_2(x_2, e))$, if $e \in \Sigma_2 \backslash \Sigma_1$

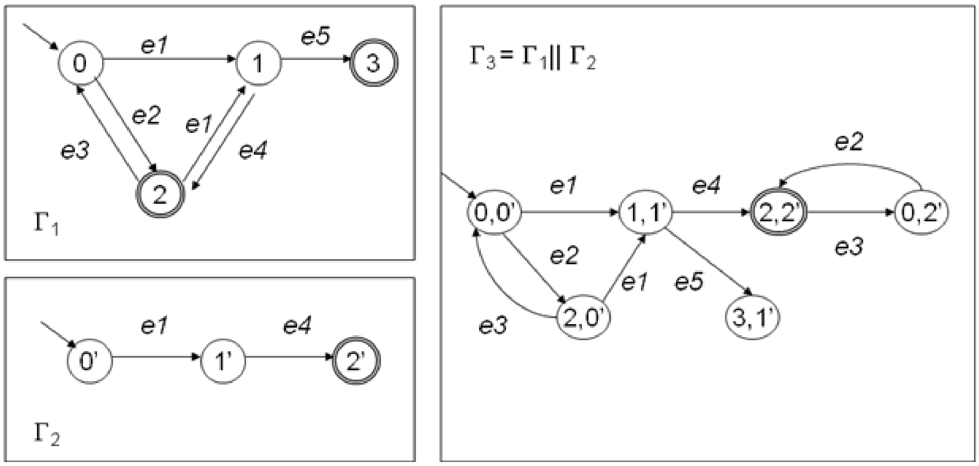
Assume $s = \Sigma_1 \cap \Sigma_2$ is the joint event set of Γ_1 and Γ_2, Γ can also be written as $\Gamma = \Gamma_1 \|_s \Gamma_2$.

Example 1 *In Figure 1, Γ_1 and Γ_2 are two automata. The third one Γ_3 is produced by synchronizing Γ_1 and Γ_2.*

Definition 7 *A **trajectory** of an automaton is a path of contiguous states and transitions in the automaton that begins at an initial state and ends at a final state of the automaton.*

Example 2 *The trajectories in the automaton Γ_3 in Figure 1 can be represented as these two*

Figure 1. An example of synchronization



formulas, in which [] means the content in [] repeated 0 or more times:*

$$[(0,0') \xrightarrow{e2} (2,0') \xrightarrow{e3}]^*[(0,0') \xrightarrow{e1} (1,1') \xrightarrow{e4} (2,2')][\xrightarrow{e3} (0,2') \xrightarrow{e2} (2,2')]^*,$$

$$[(0,0') \xrightarrow{e2} (2,0') \xrightarrow{e3}]^*[(0,0') \xrightarrow{e2} (2,0') \xrightarrow{e1} (1,1') \xrightarrow{e4} (2,2')][\xrightarrow{e3} (0,2') \xrightarrow{e2} (2,2')]^*.$$

Definition 8 ***Concatenation*** *between two automata* $\Gamma_1 = \langle X_1, \Sigma_1, T_1, I_1, F_1\rangle$ *and* $\Gamma 2 = \langle X_2, \Sigma_2, T_2, I_2, F_2\rangle$*, with* $\Sigma_1 \cap \Sigma_2 = \varnothing$ *and* $F_1 \cap I_2 \neq \varnothing$*, produces an automaton* $\Gamma=\Gamma_1 \circ \Gamma_2$*, where* $\Gamma = \langle X_1 \cup X_2, \Sigma_1 \cup \Sigma_2, T_1 \cup T_2, I_1, F_2 \cup (F_1 \backslash I_2)\rangle$.

The principle of diagnosis using DES models was founded by (Sampath, Sengupta, Lafortune, Sinnamohideen, & Teneketzis, 1995) and (Cordier & Thiébaux, 1994). System description *SD* models both correct and faulty behavior of a system. Assume system description *SD* is an automaton Γ, and observed events in chronological order are represented as another automaton *OBS*. Assume the joint event set of Γ and *OBS* is s. In this context, we call Diagnosis the automaton produced by synchronizing Γ and *OBS*:

$$\text{Diagnosis} = \Gamma \|_s OBS \qquad (1)$$

From the definition of synchronization, it is easy to prove that each trajectory in Diagnosis explains the sequence of observations in the sense that observable events in the trajectory occur in the identical chronological order as in *OBS*, that is:

$$\text{Diagnosis} \models OBS \qquad (2)$$

Therefore, Diagnosis for DES is what is called an *abductive diagnosis* in MBD theory.

Example 3 *In Figure 1,* Γ_1 *is a system description in which* e_2 *and* e_3 *represent occurrences of faults which are not observable directly (otherwise, the diagnosis would be trivial).* Γ_2 *is an observation in which two events* e_1 *and* e_4 *are observed sequentially. The* Diagnosis *is* Γ_3.

It is not so easy to compute the trajectories of Diagnosis because there are several possibilities for trajectory expansion that can arise from partial observations. We need to get all the possible trajectories. For trajectory expansion, people basically use search algorithms. Other algorithms, rooted from search algorithms, can also be used. For example, planning tools and model checking tools are used for trajectory expansion. Of course, these tools have to be modified in order to get complete trajectories.

Diagnostic process is almost achieved when Diagnosis is obtained, because Diagnosis explains the observations based on SD (as an automaton Γ). If we want to obtain diagnoses {D} as mode assignments as in the consistency-based framework, we need a mapping function f: Diagnosis $\rightarrow \{D\}$. Each trajectory t in Diagnosis is mapped into a D, that is, $t \rightarrow D$. As domain knowledge, a faulty event e_f is known to be associated with a fault mode $F(c_i)$ of some component c_i, that is, $e_f \leftrightarrow F(c_i)$[2]. If e_f is included in a trajectory t, we deduce that the correspondent fault $F(c_i)$ occurs. Formally,

Proposition 1 *Assume t is a trajectory in* Diagnosis*, then $t \rightarrow D$ where mode assignment D is defined by $D_f = \{c_j \mid e_f \leftrightarrow F(c_j) \text{ and } e_f \in t\}$ (and thus $D_{ok} = \{c_j \mid c_j \in COMPS \backslash D_f\}$).*

As each fault event maps to a fault, practically we need only to know the set of faulty events in a trajectory:

$$t \rightarrow \{e_f \mid e_f \in t\} \quad (3)$$

From (3), if we know $\{e_f\}$, we can easily get D_f and thus D. In the following, we use $\{e_f\}$ to represent a D_f. As there are often multiple trajectories $\{t^i\}$ in Diagnosis, the diagnoses $\{D^i\}$ are also multiple:

Proposition 2 *Assume $\{t_i\}$ is the set of all trajectories in* Diagnosis*, then $\{t^i\} \rightarrow \{D^i\}$, where $D_f^i = \{c_j \mid e_f^i \leftrightarrow F(c_j) \text{ and } e_f^i \in t^i\} \subseteq D^i$.*

In general, we are interested only in minimal diagnoses, that is, in Proposition 2 we keep only those D_f^i which are minimal.

Example 4 *From Diagnosis Γ_3 in Figure 1, we get 2 kinds of possible sequences of faulty events:*

{[*e*2, *e*3]*, [*e*3, *e*2]*}, {[*e*2, *e*3]*, *e*2, [*e*3, *e*2]*}.
From the above sequences, we can get three diagnoses: {}, {*e*2}, {*e*2, *e*3}. *The minimal diagnosis is* {}, *which means no fault.*

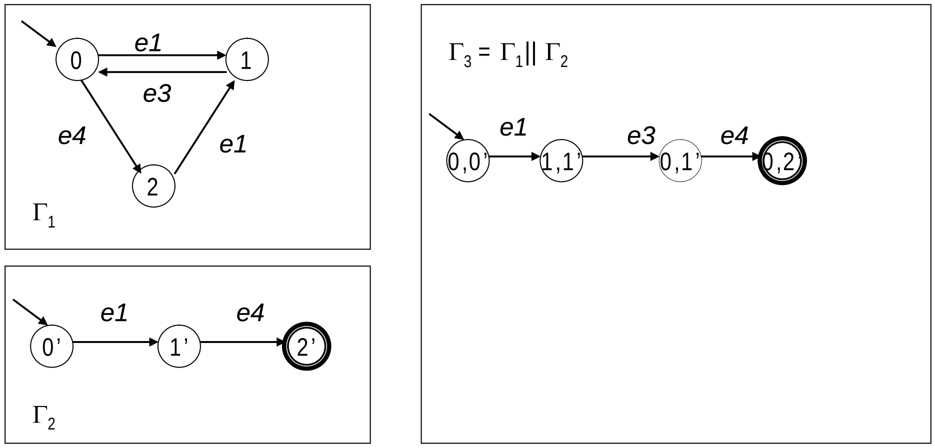
In Example 4, different trajectories give us different diagnoses. It can be no faults, or *e*2 (mapped to its fault), or both *e*2 and *e*3. They are all sound. Adding more observables is a way to clarify the ambiguity. To determine the observables for diagnosing a certain fault is the problem of diagnosability which is not covered in this article. Another example without ambiguity:

Example 5 *In Figure 2, Γ_1 is SD and Γ_2 is OBS. Γ_3 is* Diagnosis*. Since e3 is within the only trajectory, we can deduce that a fault represented by e3 occurred.*

We need to point out that the existing diagnosis methods for physical systems modeled as DES are not in general suitable for Web service processes. First, we cannot enumerate faults in Web service environments because we do not know how a Web service can be faulty if it belongs to another company. Second, it is relatively easy to keep a record for how the software is executed by recording any selected variables. In contrast, it is more difficult to insert a sensor in a physical system. Therefore it is very difficult to reconstruct the trajectories for a physical system, but it is not a key issue for diagnosing a Web service process. We will discuss the diagnosis of Web services in the Model-based Diagnosis for Web Service Processes section.

Several advances have recently been made: the decentralized diagnoser approach (Pencolé & Cordier, 2005) (a diagnosis system based on several interacting DESs); the incremental diagnosis approach (Grastien, Cordier, & Largouët, 2005) (a monitoring system that online updates

Figure 2. An example of Diagnosis



diagnosis over time given new observations); active system approaches (Baroni, Lamperti, Pogliano, & Zanella, 1999) (approaches that deal with hierarchical and asynchronized DESs); and diagnosis on reconfigurable systems (Grastien, Cordier, & Largouët, 2004). The existing techniques, such as the diagnoser approach (Pencolé, Cordier, & Rozé, 2002) or the silent closure (Baroni et al., 1999), reconstruct the unobservable behavior of the system that are required to compute diagnoses.

MODELING WEB SERVICE PROCESSES WITH DISCRETE-EVENT SYSTEMS

Description of the Web Service Processes

BPEL is an XML-based orchestration language developed by IBM and recognized by OASIS (Andrews et al., 2003). BPEL is a so-called executable language because it defines the internal behavior of a Web service process, as compared to choreography languages that define only the interactions among the Web services and are not executable.

BPEL defines fifteen activity types. Some of them are *basic activities*; the others are *structured activities*. Among the basic activities, the most important are the following:

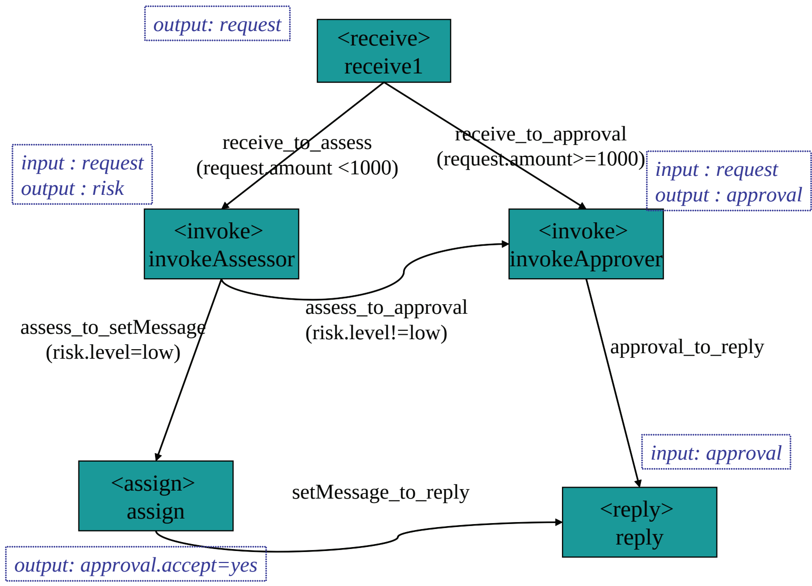
1. the ⟨receive⟩ activity is for accepting the triggering message from another Web service;
2. the ⟨reply⟩ activity is for returning the response to its requestor;
3. the ⟨invoke⟩ activity is for invoking another Web service.

The structured activities define the execution orders of the activities inside their scopes. For example:

- Ordinary sequential control between activities is provided by ⟨sequence⟩.
- Concurrency and synchronization between activities is provided by ⟨flow⟩.
- Loop is provided by ⟨while⟩.
- Nondeterministic choice based on external events is provided by ⟨pick⟩ and ⟨switch⟩.

Execution orders are also modified by defining the synchronization links between two activities (cf. Synchronization Links of Activities section).

Figure 3. A loan approval process. Activities are represented in shaded boxes. The inVar and outVar are respectively the input and output variables of an activity.



Normally, BPEL has one entry point to start the process and one point to exit, though multiple entry points are allowed. The variables in BPEL are actually the Simple Object Access Protocol (SOAP) messages defined in Web Service Description Language (WSDL). Therefore, the variables in BPEL are objects that have several attributes (called "parts" in WSDL).

An Example: the Loan Approval Process

Example 6 *The loan approval process is an example described in the BPEL Specification 1.1 (Andrews et al., 2003). It is diagrammed in Figure 3.*

This process contains five activities (big shaded blocks). An activity involves a set of input and output variables (dotted box besides each activity). All the variables are of composite type. The edges show the execution order of the activities. When two edges are issued from the same activity, only one edge that satisfies a triggering condition (shown on the edge) will be activated. In this example, the process is triggered when a ⟨receive⟩ activity named *receive1* receives a message of a predefined type. First, *receive1* initializes a variable *request*. Then, *receive1* dispatches the request to two ⟨invoke⟩ activities, *invokeAssessor* and *invokeApprover*, depending on the amount of the loan. In the case where the amount is large (*request.amount* >= 1000), *invokeApprover* is called for a decision. In the case where the amount is small (*request.amount* < 1000), *invokeAssessor* is called for risk assessment. If *invokeAssessor* returns with an assessment that the risk level is low (*risk.level = low*), a reply is prepared by an ⟨assign⟩ activity and later sent out by a ⟨reply⟩ activity. If the risk level is not low, *invokeApprover* is invoked for a final decision. The result from *invokeApprover* is sent to the client by the ⟨reply⟩ activity.

Modeling Web Services Process with Discrete-Event Systems

A Web service process defined in BPEL is a composition of activities. We are going to model a BPEL activity as an automaton. A BPEL code has a finite set of variables and a BPEL state is associated with an assignment of these variables. A BPEL activity is triggered when its initial state satisfies a finite set of triggering conditions which is a certain assignment of variables. After an activity is executed, the values of the state variables are changed. We need to extend the classic automaton definition to include the operations on state variables.

Assume a BPEL process has a finite set of variables $V = \{v_1, ..., v_n\}$, and the domain $D = \{D_1, ..., D_n\}$ for V is real values $\mathbf{R}$ or arbitrary strings. $C = \{c_1, ..., c_m\}$ is a finite set of constraints. A constraint c_j of some arity k is defined as a subset of the cartesian product over variables $\{v_{ji}, ..., v_{jk}\} \subseteq V$, that is, $c_j \subseteq D_{j1} \times \cdots \times D_{jk}$, or a first order formula over $\{v_{ji}, ..., v_{jk}\}$. A constraint restricts the possible values of the k variables.

A BPEL state s is defined as an assignment of variables. A BPEL transition t is an operation on the state s_i, that is,, $(s_j, post(V_2)) = t(s_i, e, pre(V_1))$, where $V_1 \subseteq V$, $V_2 \subseteq V$, $pre(V_1) \subseteq C$ is a set of preconditions that s_i has to satisfy and $post(V_2) \subseteq C$ is a set of post-conditions that the successor state s_j will satisfy. In another word, the transition t is triggered only when the starting state satisfies the preconditions, and the operation of this transition results in a state that satisfies the post-conditions. If a state s satisfies a constraint c, we annotate as $c \wedge s$. Then, the semantics of transition t is also represented as:

$$t : (s_i \wedge pre(V_1)) \xrightarrow{e} (s_j \wedge post(V_2)).$$

Definition 9 *A **BPEL activity** is an automaton* $\langle X, \Sigma, T, I, F, C\rangle$*, where C is a constraint set that defines states X and T*: $X \times \Sigma \times 2^C \rightarrow X \times 2^C$.

Modeling Basic Activities

In the following, we enumerate the model for each basic activity.

Activity ⟨receive⟩: $\langle\{s_o, s_f\}, \{received\}, \{t\}, \{s_o\}, \{s_f\}, C\rangle$ with
$t : (s_o \wedge SoapMsg.type = MsgType) \xrightarrow{received} (s_f \wedge RecMsg = SoapMsg)$, where *MsgType* is a predefined message type. If the incoming message *SoapMsg* has the predefined type, *RecMsg* is initialized as *SoapMsg*.

Activity ⟨reply⟩: $\langle\{s_o, s_f\}, \{replied\}, \{t\}, \{s_o\}, \{s_f\}, C\rangle$ with
$t : (s_o \wedge exists(RepMsg)) \xrightarrow{replied} (SoapMsg = RepMsg \wedge s_f)$, where $exists(RepMsg)$ is the predicate checking that the replay message *RepMsg* is initialized. *SoapMsg* is the message on the wire.

Activity ⟨invoke⟩
Synchronous invocation: $\langle\{s_o, wait, s_f\}, \{invoked, received\}, \{t_1, t_2\}, \{s_o\}, \{s_f\}, C\rangle$with
$t_1 : (s_o \wedge exists(InVar)) \xrightarrow{invoked} (wait)$, and
$t_2 : (wait \wedge SoapMsg.type = MsgType) \xrightarrow{received} (s_f \wedge exists(OutVar))$ where *InVar* and *OutVar* are the input and output variables.
Asynchronous invocation: $\langle\{s_o, s_f\}, \{invoked\}, \{t\}, \{s_o\}, \{s_f\}, C\rangle$ with
$t : (s_o \wedge exists(InVar)) \xrightarrow{invoked} (s_f)$,
asynchronous invocation does not wait for a return message.

Activity ⟨assign⟩: $\langle\{s_o, s_f\}, \{assigned\}, \{t\}, \{s_o\}, \{s_f\}, C\rangle$ with
$t : (s_o \wedge exists(InVar)) \xrightarrow{assigned} (s_f \wedge OutVar = InVar)$

Activity ⟨throw⟩: $\langle\{s_o, s_f\}, \{thrown\}, \{t\}, \{s_o\}, \{s_f\}, C\rangle$ with
$t : (s_o \wedge Fault.mode = Off) \xrightarrow{thrown} (s_f \wedge Fault.mode = On)$

Activity ⟨wait⟩: ⟨$\{s_o, wait, s_f\}$, $\{waiting, waited\}$, $\{t_1, t_2\}$, $\{s_o\}$, $\{s_f\}$, C⟩ with

$t_1 : (s_o \wedge Wait\_mode = Off) \xrightarrow{waiting} (wait \wedge Wait\_mode = On)$

$t_2 : (wait \wedge Wait\_mode = On) \xrightarrow{waited} (s_f \wedge Wait\_mode = Off)$

This model is not temporal. We do not consider time, so the notion of delay is not considered in this activity.

Activity ⟨empty⟩: ⟨$\{s_o, s_f\}$, $\{empty\}$, $\{t\}$, $\{s_o\}$, $\{s_f\}$, C⟩

$t : (s_o) \xrightarrow{empty} (s_f)$

Modeling Structured Activities

Structured activities nest other activities. We can model the structured activities as automata. Note that any automaton modeling a basic activity or a structured activity has only one initial state and one final state. In the following are the automata for the structured activities.

Sequence

A ⟨sequence⟩ can nest n activities ⟨A_i⟩ in its scope. These activities are executed in sequential order. Assume ⟨A_i⟩ : ⟨S_{Ai}, Σ_{Ai}, T_{Ai}, $\{s_{Aio}\}$, $\{s_{Aif}\}$, C_{Ai}⟩, $i \in \{1, ..., n\}$.

Activity ⟨sequence⟩: ⟨$\{s_o, s_f\} \cup \bigcup S_{Ai}$, $\{end\} \cup \bigcup \{callA_i\} \cup \bigcup \Sigma_{Ai}$, $\{t_i\} \cup \bigcup T_{Ai}$, $\{s_o\}$, $\{s_f\}$, $\bigcup C_{Ai}$⟩ with

$t_0 : (s_o) \xrightarrow{callA_1} (s_{A1o})$

$t_i : (s_{Aif}) \xrightarrow{callA_{i+1}} (s_{Ai+1o})$

$t_n : (s_{Anf}) \xrightarrow{end} (s_f)$

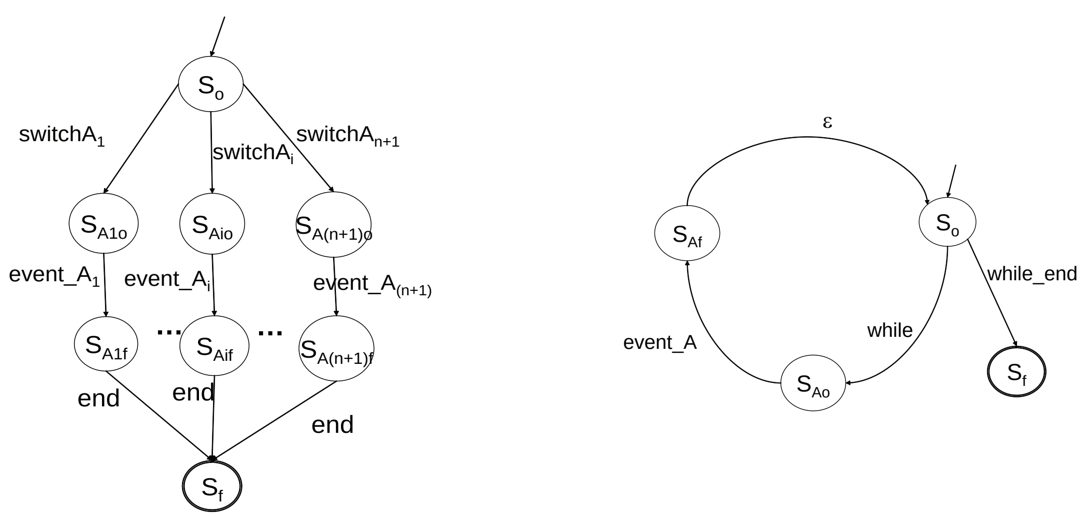
If assume $s_o = s_{A1o}$, $s_f = s_{Anf}$, and $s_{Aif} = s_{Ai+1o}$, for $i = [1, ..., n\text{-}1]$, a short representation of ⟨sequence⟩ is the concatenation of the nested activities A1◦A2 ⋯ ◦An.

Switch

Assume a ⟨switch⟩ has n ⟨case⟩ branches and one ⟨otherwise⟩ branch (see Figure 4(a)). Assume ⟨A_i⟩ : ⟨S_{Ai}, Σ_{Ai}, T_{Ai}, $\{s_{Aio}\}$, $\{s_{Aif}\}$, C_{Ai}⟩, i $\in \{1, ..., n+1\}$.

Activity ⟨switch⟩: ⟨$\{s_o, s_f\} \cup \bigcup S_{Ai}$, $\{end\} \cup \bigcup \{switchA_i\} \cup \bigcup \Sigma_{Ai}$, $\bigcup \{t_{io}\} \cup \bigcup \{t_{if}\} \cup \bigcup T_{Ai}$, $\{s_o\}$, $\{s_f\}$, $\bigcup C_{Ai}$, $\cup \bigcup pre(V_i)$⟩.

Figure 4. The automata for ⟨switch⟩ and ⟨while⟩



(a)The automaton for ⟨switch⟩ *(b)The automaton for ⟨while⟩*

Assume V_1, ..., V_n are variable sets on n ⟨case⟩ branches, $pre(V_1), \ldots, pre(V_n)$ are the constraints defined by the attributes condition in ⟨case⟩. The transitions are defined as:

$$t_{io} : (s_o \wedge \neg pre(V_1) \wedge \cdots \wedge pre(V_i) \cdots \wedge \neg pre(V_n)) \xrightarrow{switchA_i} (s_{Aio}), \forall i \in \{1, ..., n\}$$
$$t_{(n+1)o} : (s_o \wedge \neg pre(V_1) \wedge \cdots \wedge \neg pre(V_i) \cdots \wedge \neg pre(V_n)) \xrightarrow{switchA_{n+1}} (s_{A(n+1)o})$$
$$t_{if} : (s_{Aif}) \xrightarrow{end} (s_f), \forall i \in \{1,..., n+1\}$$

While Assume ⟨while⟩ nests an activity ⟨A⟩: ⟨S_A, Σ_A, T_A, $\{s_{Ao}\}$, $\{s_{Af}\}$, C⟩ (see Figure 4(b)).
Activity ⟨while⟩: $\{s_o, s_f\} \cup S_A$, $\{while, while\_end\} \cup \Sigma_A$, $\{t_o, t_f, t\} \cup T_A$, $\{s_o\}$, $\{s_f\}$, $C \cup pre(W)$⟩.

Assume W is a variable set, and $pre(W)$ is the constraint defined by the attribute condition in ⟨while⟩.

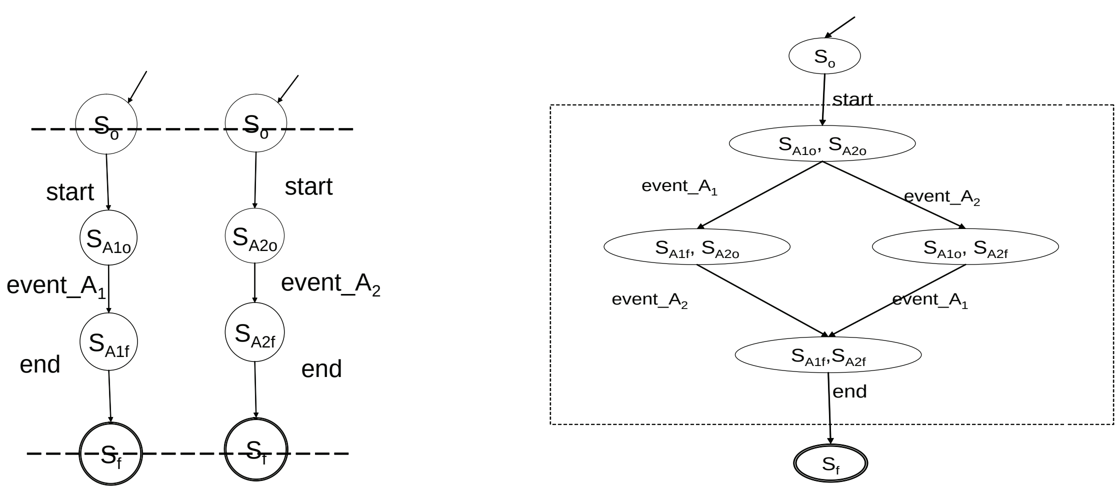
$$t_o : (s_o \wedge pre(W)) \xrightarrow{while} (s_{Ao})$$
$$t_f : (s_o \wedge \neg pre(W)) \xrightarrow{while\_end} (s_f)$$
$$t : (s_{Af}) \xrightarrow{\varepsilon} (s_o)$$

Flow
A ⟨flow⟩ can nest n activities ⟨A_i⟩ in its scope. These activities are executed concurrently. Assume ⟨A_i⟩ : ⟨S_{Ai}, Σ_{Ai}, T_{Ai}, $\{s_{Aio}\}$, $\{s_{Aif}\}$, C_{Ai}⟩, i $\in\{1, ..., n\}$.
Activity ⟨flow⟩: ⟨$\{s_o, s_f\} \cup \bigcup S_{Ai}$, $\{start, end\} \cup \bigcup \Sigma_{Ai}$, $\bigcup \{t_{io}, t_{if}\} \cup \bigcup T_{Ai}$, $\{s_o\}$, $\{s_f\}$, $\bigcup C_{Ai}$⟩ with

$$t_{io} : (s_o) \xrightarrow{start} (s_{Aio})$$
$$t_{if} : (s_{Aif}) \xrightarrow{end} (s_f)$$

Notice that the semantic of automata cannot model concurrency. We actually model the n-paralleled branches into n automata and define synchronization events to build their connections. The principle is illustrated in Figure 5. At the left, each branch is modeled as an individual automaton. The entry state s_o and the end state s_f are duplicated in each branch. Events *start* and *end* are the synchronization events. At the right is the automaton resulted by synchronization. More complicated case in joining the paralleled branches is discussed in subsection Synchronization Links of Activities. The key point in reasoning about decentralized automata is to postpone the synchronization until a synthesis result is needed,

Figure 5. Build concurrency as synchronized DES pieces



(a) Concurrency branches for DES pieces

(b) The joint DES model

in order to avoid the state explosion problem (Pencolé et al., 2002; Pencolé & Cordier, 2005). In Web service diagnosis, it is the situation (cf. subsection Multiple Exceptions).

Pick

Assume a ⟨Pick⟩ has n ⟨onMessage⟩ and one ⟨onAlarm⟩ branches. ⟨onMessage⟩ branches are triggered by predefined events. Assume activities $\{A_1,..., A_n\}$ are corresponding to the n branches respectively. ⟨onAlarm⟩ branch is triggered by a time-out event produced by a timer. Assume activity A_{n+1} is corresponding to ⟨onAlarm⟩ branch. Exactly one branch will be selected based on the occurrence of the event associated with before any others. Assume $\langle A_i \rangle : \langle S_{Ai}, \Sigma_{Ai}, T_{Ai}, \{s_{Aio}\}, \{s_{Aif}\}, C_{Ai}\rangle$, i $\in \{1, ..., n+1\}$.

Activity ⟨pick⟩: $\langle \{s_o, s_f\} \cup \bigcup S_{Ai}, \bigcup\{start_{Ai}\} \cup \{end\} \cup \bigcup \Sigma_{Ai}, \bigcup\{t_{io}, t_{if}\} \cup \bigcup T_{Ai}, \{s_o\}, \{s_f\}, \bigcup C_{Ai} \cup \bigcup exists(\ event_{Ai})\rangle$ with

$t_{io} : (s_o \wedge exists(event_{Ai})) \xrightarrow{start_{Ai}} (s_{Aio})$

$t_{if} : (s_{Aif}) \xrightarrow{end} (s_f)$

Synchronization Links of Activities

Each BPEL activity can optionally nest the standard elements ⟨source⟩ and ⟨target⟩. The XML grammar is defined as:

<*source linkName* =“*ncname*” *transitionCondition* = “*bool − expr*”?/>

<*target linkName* =“*ncname*”/>

A pair of ⟨source⟩ and ⟨target⟩ defines a link which connects two activities. The target activity must wait until the source activity finishes. Therefore, links define the sequential orders of activities. When one ⟨flow⟩ contains two parallel activities which are connected by a link, the two activities become sequentially ordered. An activity may have multiple ⟨source⟩ or ⟨target⟩ elements. Links can express richer logics, but they make the processes more difficult to analyse.

⟨source⟩ can be modeled similarly like an ⟨activity⟩, with “*transitionCondition*” as the triggering condition.

Activity ⟨source⟩: $\langle\{s_o, s_f\}, \{\varepsilon\}, \{t\}, \{s_o\}, \{s_f\},$ *transitionCondition*⟩ with

$t : (s_o \wedge transitionCondition) \xrightarrow{\varepsilon} (s_f)$,

When an activity is the ⟨target⟩ of multiple links, a join condition is used to specify how these links can join. The join condition is defined within the activity. BPEL specification defines standard attributes for this activity:

<*activityName* =“*ncname*”, *joinCondition* =“*bool − expr*”, *suppressJoinF ailure* =“*yes|no*”/>

where *joinCondition* is the logical OR of the liveness status of all links that are targeted at this activity. If the condition is not satisfied, the activity is bypassed, and a fault is thrown if *suppressJoinFailure* is no.

In this case, the synchronization event end as in Figure 5(a) is removed. If the ending state of ⟨flow⟩ is the starting state s_o’ of the next activity, the precondition of s_o’ is the *joinCondition*. For example, either of the endings of the two branches can trigger the next activity can be represented as: $s_o' \wedge (exists(s_{A1f}) \vee exists(s_{A2f}))$.

Modeling the Loan Approval Process

In this section, we present the complete DES model for the process in Example 6.

Example 7 *The loan approval process in Example 6 contains five activities:* ⟨receive1⟩, ⟨invokeAssessor⟩, ⟨invokeApprover⟩, ⟨assign⟩, ⟨reply⟩. *The five activities are contained in a* ⟨flow⟩. *Six links*, ⟨receive_to_assess⟩, ⟨receive_to_approval⟩, ⟨assess_to_setMessage⟩,

$\langle$assess_to_approval$\rangle$, $\langle$approval_to_reply$\rangle$, *and* $\langle$setMessage_to_reply$\rangle$, *connect the activities and change the concurrent orders to sequential orders between the activities. In this special case, there are actually no concurrent activities. Therefore, for clarity, the event caused by* $\langle$flow$\rangle$ *is not shown. Assume the approver may return an error message due to an unknown error. Here is the formal representation of the process (also reference to Figure 6).*

$\langle$receive1$\rangle$ = $\langle\{x_0, x_1\}, \{received\}, \{t_1\}, \{x_0\}, \{x_1\}, C\rangle$, with

$t_1 : (x_0 \wedge SoapMsg.type = MsgType) \xrightarrow{received} (x_1 \wedge request = SoapMsg)$, where

MsgType is a predefined message type. If the incoming message *SoapMsg* has the predefined type, request is initialized as *SoapMsg.*

$\langle$receive_to_assess$\rangle$ = $\langle\{x_1, x_2\}, \{\varepsilon\}, \{t_2\}, \{x_1\}, \{x_2\}, C\rangle$, with

$t_2 : (x_1 \wedge request.amount < 1000) \xrightarrow{\varepsilon} (x_2)$.

$\langle$receive_to_approval$\rangle$ = $\langle\{x_1, x_3\}, \{\varepsilon\}, \{t_3\}, \{x_1\}, \{x_3\}, C\rangle$, with

$t_3 : (x_1 \wedge request.amount \geq 1000) \xrightarrow{\varepsilon} (x_3)$.

$\langle$invokeAssessor$\rangle$ = $\langle\{x_2, x_4, x_5\}, \{invoked\_assessor, received\_risk\}, \{t_4, t_5\}, \{x_2\}, \{x_5\}, C\rangle$ with

$t_4 : (x_2 \wedge InVar = request) \xrightarrow{invoked\_assessor} (x_4)$, and

$t_5 : (x_4) \xrightarrow{received\_risk} (x_5 \wedge OutVar = risk)$ where *InVar* and *OutVar* are the input and output variables.

$\langle$assess_to_setMessage$\rangle$ = $\langle\{x_5, x_6\}, \{\varepsilon\}, \{t_6\}, \{x_5\}, \{x_6\}, C\rangle$, with

$t_6 : (x_5 \wedge risk.level = low) \xrightarrow{\varepsilon} (x_6)$.

$\langle$assess_to_approval$\rangle$ = $\langle\{x_5, x_3\}, \{\varepsilon\}, \{t_7\}, \{x_5\}, \{x_3\}, C\rangle$, with

$t_7 :(x_5 \wedge risk.level = high) \xrightarrow{\varepsilon} (x_3)$.

$\langle$invokeApprover$\rangle$ = $\langle\{x_3, x_7, x_8\}, \{invoked\_approver, received\_approval, received\_aplError\}, \{t_8, t_9, t_e\}, \{x_3\}, \{x_8\}, C\rangle$ with

$t_8 : (x_3 \wedge InVar = request) \xrightarrow{invoke\_approver} (x_7)$, and

$t_9 : (x_7) \xrightarrow{received\_approval} (x_8 \wedge OutVar = approval)$, and

$t_e : (x_7) \xrightarrow{received\_aplError} (x_8 \wedge OutVar = errorMessage)$ where

InVar and *OutVar* are the input and output variables.

$\langle$assign$\rangle$: $\langle\{x_6, x_9\}, \{assigned\}, \{t_{10}\}, \{x_6\}, \{x_9\}, C\rangle$ with

$t_{10} : (x_6) \xrightarrow{assigned} (x_9 \wedge approval.accept = yes)$

$\langle$setMessage_to_reply$\rangle$ = $\langle\{x_9, x_{10}\}, \{\varepsilon\}, \{t_{11}\}, \{x_9\}, \{x_{10}\}, C\rangle$, with

$t_{11} : (x_9) \xrightarrow{\varepsilon} (x_{10})$.

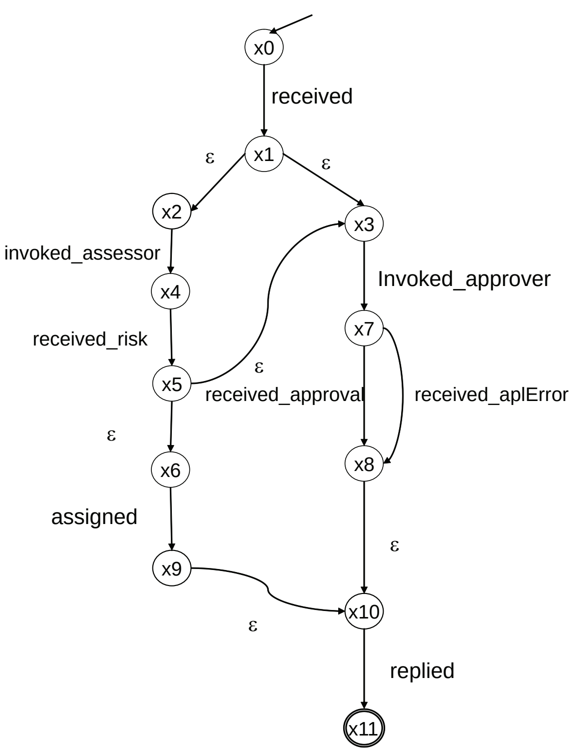
$\langle$approval_to_reply$\rangle$ = $\langle\{x_8, x_{10}\}, \{\varepsilon\}, \{t_{12}\}, \{x_8\}, \{x_{10}\}, C\rangle$, with

$t_{12} : (x_8) \xrightarrow{\varepsilon} (x_{10})$.

$\langle$reply$\rangle$: $\langle\{x_{10}, x_{11}\}, \{replied\}, \{t_{13}\}, \{x_{10}\}, \{x_{11}\}, C\rangle$ with

$t_{13} :(x_{10} \wedge exists(approval)) \xrightarrow{replied} (x_{11} \wedge SoapMsg = approval)$, where *SoapMsg* is the message on the wire.

Figure 6. Automaton modeling loan approval process



MODEL-BASED DIAGNOSIS FOR WEB SERVICE PROCESSES

A Web service process can run down for many reasons. For example, a composed Web service may be faulty, an incoming message mismatches the interface, or the Internet is down. The diagnosis task is to determine the Web services responsible for the exceptions. These Web services will be diagnosed faulty. In this article, our major effort is on diagnosing business logic-related exceptions.

In our framework, *COMPS* is made up of all the basic activities of the Web service process considered, and *OBS* is made up of the exceptions thrown and the events of the executed activities. These events can be obtained by the monitoring function of a BPEL engine. A typical correct model for an activity $\langle A \rangle$ is thus:

$$\neg ab(A) \land \neg ab(A.input) \Rightarrow \neg \mathrm{ab(A.output)} \quad (4)$$

For facilitating diagnosis, the BPEL engine has to be extended for the following tasks: 1) record the events emitted by executed activities; 2) record the input and output SOAP messages; and 3) record the exceptions and trigger the diagnosis function when the first exception is received. ***Diagnosing*** is triggered on the first occurred exception[3]. The MBD approach developed relies on the following three steps with the techniques we introduced in the content above.

1. A prior process modeling and variable dependency analysis

All the variables in BPEL are global variables, that is, they are accessible by all the activities. An activity can be regarded as a function that takes input variables and produces output variables. An activity has two kinds of relation to its input and output variables: defining and utilizing. We use *Def*(A, V) and *Util*(A, V) to present the relation that activity A defines variable V or utilizes V. An activity is normally a utilizer of its input variables, and is a definer of its output variables. This is similar to the viewpoint of programming slicing, a technique in software engineering for software debugging (cf. subsection A Brief Comparison to Program Slicing). But BPEL can violate this relation by applying some business logic. For example, some variables, such as order ID and customer address, are not changeable after they are initialized in a business process. Therefore, a BPEL activity may be a utilizer of its output variables. In BPEL, it is defined in *correlation sets.* In this case, we use *Util*(A, ($V1$, $V2$)) to express that output $V2$ is correlated to input $V1$. In this case, Formula 4 can be simplified as:

$$\neg ab(A.input) \Rightarrow \neg ab(A.output), \text{ if } Util(A, (A.input, A.output)) \quad (5)$$

In Example 8, we give a table to summarize the variable dependency for the load approval process. This table can be obtained automatically from BPEL. The approach is not presented due to lack of space.

Example 8 *The variable dependency analysis for the loan approval process is in Table 1.*

2. Trajectories reconstruction from observations after exceptions are detected

As mentioned earlier, the observations are the events and exceptions when a BPEL process is executed. The events can be recovered from the log file in a BPEL engine. The observations are formed in an automaton. The possible trajectories of the process are calculated by synchronizing the automaton of the observations with the automaton of the system description:

$$\text{trajectories} = \textit{trajectories of } SD||OBS \quad (6)$$

Table 1. The variable dependency analysis for the loan approval process

Variables	Parts	Definer	Utilizer
request	firstname lastname amount	receive1 receive1 receive1	invokeAssessor, invokeApprover invokeAssessor, invokeApprover invokeAssessor, invokeApprover
risk	level	invokeAssessor	
approval	accept	assign, invokeApprover	reply
error	errorCode	invokeApprover	

We do not require recording each event during the execution, but just enough to be able to identify the real trajectory of the process. This is very useful when some events are not observable and when there are too many events to record. Reference to the subsection Without Full Observability for more discussion.

Example 9 *In the loan approval example, assume that OBS={received, invoked_assessor, received_risk, invoked_approver, received_aplErr} (as in Figure 7(a)). Received_aplErr is an exception showing that there is a type mismatch in received parameters. We can build the trajectory of evolution as shown, also shown in Figure 7(b).*

$$(x_0) \xrightarrow{received} (x_1) \xrightarrow{\varepsilon} (x_2) \xrightarrow{invoked\_assessor} (x_4) \xrightarrow{received\_risk} (x_5) \xrightarrow{\varepsilon} (x_3) \xrightarrow{invoked\_approver} (x_7) \xrightarrow{received\_aplErr} (x_8)$$

3. Accountability analysis for mode assignment

Not all the activities in a trajectory are responsible for the exception. As a software system, the activities connect to each other by exchanging variables. Only the activities which change the attributes within a variable can be responsible for the exception.

Assume that activity A generates exception e_f, and t is a trajectory ending at A. The responsibility propagation rules are (direct consequences of the contraposition of Formula 4 and 5):

$$e_f \in \Sigma_A \ |\text{-}\ ab(A) \vee \vee\{ab(A.InVar.part) | A.InVar.part \in A.InVar\} \quad (7)$$

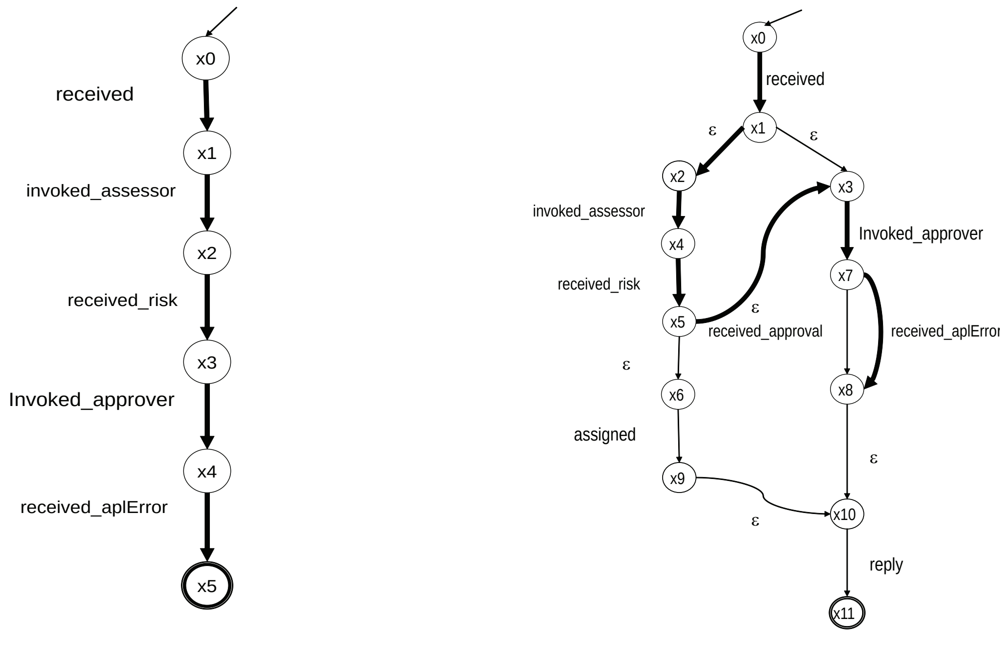
$\forall A_i, A_j \in t, A_j \neq A_i$, A_j is the only activity between A_j and A_i such that $Def(A_j, A_i.InVar.part)$,

$$ab(Ai.InVar.part) \ |\text{-}\ ab(A_j) \vee \vee\{ab(A_j.InVar.part) | A_j.InVar.part \in A_j.InVar\} \quad (8)$$

The first rule in (7) states that if an activity A generates an exception e_f, it is possible that activity A itself is faulty, or any part in its *A.InVar* is abnormal. Notice a variable is a SOAP message which has several parts. *A.InVar.part* is a part in *A.InVar*[4]. The second rule in (8) propagates the responsibility backwards in the trajectory. It states that an activity $A_j \in t$ that defines a part of A_i.*InVar* which is known as faulty could be faulty; and its inputs could also be faulty. If there are several activities that define a part of A_i.*InVar*, only the last one counts, because it overrides the changes made by the other activities, that is, A_j is the last activity "between" A_j and A_i that defines A_i.*InVar*, as stated in (8). After responsibility propagation, we obtain a *responsible set* of activities $RS = \{A_i\} \subseteq t$.

The set $CO = \{A\} \cup \{A_i | A_i \in RS\}$ is a conflict set, because if all the components in *CO* are correct, there should be no exceptions. Then a diagnosis is any of A or A_i in the responsible set is faulty:

Figure 7. (a) the observations; (b) the loan approval process evolution trajectory up to the exception



(a) *(b)*

$$\{D_f\} = \{\{A\}\} \cup \{\{A_i\} | A_i \in RS\} \qquad (9)$$

Each D_f is a single fault diagnosis and the result is the disjunct of the D_f. The algorithm is as following. Lines 1-2 apply rule (7). Lines 3-8 apply rule (8). This algorithm checks each activity in *t*. Therefore the complexity of this algorithm is $O(|t|)$.

Example 10 *For the loan approval example, we have the trajectory as in Example 9. We do the responsibility propagation. As invokeApprover generates the exception, according to Formula (7), invokeApprover is possibly faulty. Then its input request is possibly faulty. Among all the activities {receive1, invokeAssessor, invokeApprover} in the trajectory, receive1 defines request, invokeAssessor and invokeApprover utilize request. Therefore, receive1 is possibly faulty, according to Formula (8). receive1 is the first activity in the trajectory. The propagation stops. The diagnosis is:*

$$\{D_f\} = \{\{receive1\}, \{invokeApprover\}\}$$

Example 10 has two single faults {*receive1*} and {*invokeApprover*} for the exception *received_aplErr*, which means either the activity ⟨receive1⟩ or ⟨invokeApprover⟩ is faulty. In an empirical way, an engineer may associate only one fault for an exception. But our approach can find all possibilities. Second, if we want to further identify which activity is indeed responsible for the exception, we can do a further test on the data. For example, if the problem is wrong data format, we can verify the data format against some specification, and then identify which activity is faulty.

Multiple Exceptions

There are two scenarios where multiple exceptions can happen. The first scenario is the chained exceptions when one exception causes the others to happen. Normally the software reports this chained relation. We need to diagnose only the first occurred exception, because the causal relations for other exceptions are obvious from the chain.

The second scenario is the case when exceptions occur independently, for example, two paralleled branches report exceptions. As the exceptions are independent, we diagnose each exception independently, the synthesis diagnoses are the union of all the diagnoses. Assume the minimal diagnoses for exception 1 are $\{D_i^1\}$, where $i \in [1, ..., n]$, and the minimal diagnoses for exception 2 are $\{D_j^2\}$, where $j \in [1, ..., m]$, the synthesis diagnoses are any combinations of D_i^1 and D_j^2: $\{D_i^1 \cup D_j^2 | i \in [1, ..., n], j \in [1, ..., m]\}$.

What interests us most is the synthesis of the minimal diagnoses. So, we remove the $D_i^1 \cup D_j^2$ that are supersets of other ones. This happens only if at least one activity is common to $\{D_i^1\}$ and $\{D_j^2\}$, giving rise to a single fault that can be responsible for both exceptions. Such activities are thus most likely to be faulty (single faults being preferred to double faults).

Without Full Observability

Equation 6 can recover trajectories from *OBS*. Actually if we can record all the events in a model, trajectories are equal to *OBS*. It is a trivial case. The problem occurs when we do not have full observability. For example, a third party BEPL engine does not allow us to record all the events crucial for diagnosis, or the process is too large to record every event. Equation 6 gets all the possible trajectories satisfying *OBS*. Therefore, this method can deal with missing events. At the meantime, if there are multiple trajectories satisfying *OBS*, the diagnoses are the union of the diagnoses obtained from all the trajectories. This can result in a larger number of diagnoses, that is, diagnosis is not precise.

It is a trade off between observability and diagnosability. Increasing observability, that is, observing more events, can result in more precise diagnosis, while increasing the observing cost. It is our future work to study the minimal observables for diagnosing a fault.

Offline Diagnosability Analysis

Diagnosability analysis is normally conducted offline without executing the processes. We do not touch diagnosability analysis problems in this article. But diagnosability is related to the method of diagnosis. Assuming an exception at a place in a BPEL process, diagnosability analysis of this exception involves calculating all the trajectories from the process entry point to the assumed exception and find diagnoses on each trajectory. The method is similar as the three steps in the Model-based Diagnosis for Web Service Processes section, just the second step is replaced by a graph traverse algorithm to compute all the trajectories between two nodes on the graph formed by the automaton model.

Multiple Trajectories

Lack of full observability and offline diagnosability analysis can cause multiple trajectories. Assume trajectories $\{t_1, ..., t_n\}$. Using our diagnosis algorithm, each trajectory t_i has conflict set CO_i. But as the trajectories are the possible execution paths, they do not occur at the same time, the conflict sets are not all contradictory at the same time. Indeed only one of these trajectories, even if which one is unknown, really happened. In this case, we do not have to use hitting set algorithm to compute diagnoses. We define simply the synthesis diagnoses as the disjunction of all the diagnoses, $\vee\{D_i\}$, which means diagnoses are in any of $\{D_i\}$.

Obtaining the Dependency Table

The variable dependency table can be automatically constructed from BPEL. Regard a BPEL activity $\langle A \rangle$ as a function $OutVar = f_A(InVar)$. Then $\langle A \rangle$ is the utilizer of *InVar* and definer of *OutVar*.

Before, we have defined $\langle A \rangle$ as an automaton. Then *InVar* is the variables used in so and *Outvar* is the variables used in s_f.

Due to some business logic, some variables, such as order ID and customer address, are not changeable after they are initialized in a business process. BPEL uses correlation set to define that two variables are identical in values. The *correlation set* is referenced by an activity. When an activity has a correlation set within its scope, the correlation indicates if this activity initiates the variables by setting the attribute initiate. If initiate is "yes", this activity is the definer for both of the variables; otherwise, this activity is the utilizer for both of the variables.

Implementation

There are many BPEL engines in the market. We extended ActiveBPEL (Active Endpoint, 2007), an open source from Active Endpoints, to implement our diagnosis mechanism. ActiveBPEL allows us to record every executed activity and messages in the execution. These activities and messages are the observations during execution and they correspond to a subset of the events and states in our formal model. Therefore, from the synchronization of the observations and the formal model result the execution trajectories. The diagnosis function is a java package that is invoked when an exception is caught. It takes the observations and the dependency table as inputs, calculates the trajectories and uses Algorithm 1 to calculate diagnoses.

RELATED WORK AND DISCUSSION

A Brief Comparison to Program Slicing

Program slicing is a well known technique in software engineering for software debugging (Weise, 1984). If we have a specific program Π, a location within this program #*n* (*n* is a number given to a line), and a variable x, then a slice is itself a program that is obtained from the original program by removing all statements that have no influence on the given variable at the specified position. Since slices are usually smaller than the original program they focus the user's attention on relevant parts of the program during

Algorithm 1. Calculate diagnosis for a faulty Web service process

INPUT: A_0 - the activity generating the exception.
t - a list of activities in a reserved trajectory ending at A_0, taken in reverse order with A_0 excluded.
Variables: *V* - a list of faulty variable parts, initialized as {}.
OUTPUT: *D* - the list of all possible faulty activities, initialized as $\{A_0\}$.
Notes about the algorithm: 1) list.next() returns the first element of a list; list.add(element) adds an element at the end of the list; list.remove(element) removes an element from the list. 2) Activity *A* has a list of input variables *A.InVars* and output variables *A.OutVars*. 3) a variable *var* has a list of parts *var.Parts*.

```
for each variable var in A0.InVars do
    V.add(var.Parts)
while A = t.next()! = null do
    if ∃p ∈ V, Def(A, p) then
        D.add(A)
        V.remove(v)
        for each variable var in A.InVars do
            V.add(var.Parts)
return D
```

debugging. Slices can be computed from Program Dependence Graph (PDG) (Ottenstein & Ottenstein, 1984) as a graph reachability problem. A PDG G_Π for a program Π is a direct graph. The vertices of G_Π represent assignment statements and control predicates that occur in program Π. In addition G_Π includes the distinguished *entry* vertex. The edges of the graph represent either control or data dependencies. Given a criterion $\langle n, x\rangle$, the slice is computed in two steps. First, the vertex *v* representing the last program position before n where variable x is defined must be localized. Second, the algorithm collects all vertices that can reach v via a control or flow dependency edge. The statements represented by the collected vertices (including vertex *v*) are equal to the program slice for Π.

Wotawa has discussed the relationship between MBD based debugging and program slicing (Wotawa, 2002). In his work, each statement in a program is viewed as a component with a mode, inputs and outputs. The logic representation of a statement #*n* is $\neg ab(n) \rightarrow out(n)= f(in(n))$, that is, if #*n* is not faulty, the output *out*(*n*) is a function of the input in(n) according to the syntax of the program. He observed that the strongly connected components in the PDG have an influence one each other. Only if all the components are not faulty, the super component composed by these components is not faulty. He defined a dependency model whose nodes are the strongly connected components in the PDG and added a logic rule to describe the relation between the super component and the components within it. Assume $\{s_1,s_2, ..., s_n\}$are strongly connected and the name of the super component is *SC*, then the rule is $\neg ab(s_1) \wedge ... \wedge\neg ab(s_n) \rightarrow \neg ab(SC)$. With the additional rule, logic deduction can more precisely identify the faulty components. Under this kind of modeling, slices of a single variable are equivalent to conflicts in MBD. And MBD and program slicing should draw equivalent conclusions on which statements are faulty.

We consider that diagnosing Web service processes is not equivalent to program debugging. First, we are interested in the faults due to the unknown behavior of the external Web services and due to the interaction between Web services. We assume that the Web service processes are described correctly in BPEL or a Web service process description language. This implicitly excludes the structured activities to be faulty. This is equivalent to consider only data dependency in program slice. Second, though Web service process description languages are like programs, they are simpler than programs. For example, they do not use pointers or other complicated data structures as in programs, and they do not use *Goto* and its other restricted forms as in unstructured program. This makes it possible that diagnosing Web service processes can be simpler than diagnosing programs.

The diagnosis method developed in this article can be compared to dynamic slicing introduced in (Korel & Laski, 1988). Similar to our method, dynamic slicing considers the bugs should be within the statements that actually affect the value of a variable at a program point for a particular execution of the program. Their solution, following after Weiser's static slicing algorithm, solves the problem using data-flow equations, which is also similar to the variable dependency analysis presented in this article, but not the same. An external Web service can be seen as a procedure in a program, with unknown behavior. For a procedure, we normally consider the outputs brought back by a procedure are generated according to the inputs. Therefore, in slicing, the outputs are considered in the definition set (the set of the variables modified by the statement). For Web services, we can know some parts in SOAP response back from a Web service should be unchanged, for example, the name and the address of a client. This relation is defined as correlation set. We should point out that the variable dependency analysis in this article is different from slicing. As a consequence, the diagnosis obtained from MBD approach in this article can be different from slicing, and actually more precise.

As MBD approach can integrate more business logic into its model, it is less rigid than slicing. In this sense, MBD is more business oriented, not program oriented, which makes it more suitable for diagnosing Web service processes than slicing.

MBD in Diagnosing Component-Based Software

Besides Wotawa's work mentioned above, some other people have applied MBD on diagnosing component-based software systems. We found that when diagnosing such systems, the modeling is rather at the component level than translating lines of statements into logic representations. Grosclaude in (Grosclaude, 2004) used a formalism based on Petri nets to model the behaviors of component-based systems. It is assumed that only some of the events are monitored. The history of execution is reconstructed from the monitored events by connecting pieces of activities into possible trajectories. Console's group is working towards the same goal of monitoring and diagnosing Web services like us. In their article (Ardissono, Console, Goy, Petrone, Picardi, & Segnan, 2005), a monitoring and diagnosing method for choreographed Web service processes is developed. Unlike BPEL in our article, choreographed Web service processes have no central model and central monitoring mechanism. (Ardissono et al., 2005) adopted grey-box models for individual Web services, in which individual Web services expose the dependency relationships between their input and output parameters to public. The dependency relationships are used by the diagnosers to determine the responsibility for exceptions. This abstract view could be not sufficient when dealing with highly interacting components. More specifically, if most of the Web services claim too coarsely that their outputs are dependent on their inputs, which is correct, the method in (Ardissono et al., 2005) could diagnose almost all the Web services as faulty. Yan et al. (Yan, Pencolé, Cordier, & Grastien, 2005) is our preliminary work to the present one, focusing on Web service modeling using transition systems. The major work in this article is to complete the monitoring and diagnosis methods and present the diagnosis algorithm. The syntax of modeling in this article is improved from (Yan et al., 2005) with simplified representation of states and explicit definition of constraints. As a result, the model for a process can be more readable and a slightly fewer states. This article is also self-contained with MBD background and discussions on fault management tasks for Web service processes.

Related Work in Web Service Monitoring, Modeling and Composition

Several groups of researchers work on Web service monitoring frameworks. (Baresi, Ghezzi, & Guinea, 2006) proposes BPEL[2] which is the original BPEL with monitoring rules. Monitoring rules define how the user wants to oversee the execution of BPEL. But (Baresi et al., 2006) does not specify the monitoring tasks. (Mahbub & Spanoudakis, 2004) proposes a framework for monitoring requirements of BPEL-based service compositions. Their approach uses event calculus for specifying the requirements that must be monitored. Requirements can be behavioral properties of the coordination process or assumptions about the atomic or joint behavior of the deployed services. Events, produced by the normal execution of the process, are stored in a database and the runtime checking is done by an algorithm based on integrity constraint checking in temporal deductive databases. These frameworks can be used for recording the events and messages used for diagnosis.

In addition to automata used in this article, Petri nets and process algebra are also used as formal models for Web service processes. For example, (Ferrara, 2004; Salaün, Bordeaux, &

Schaerf, 2004; Viroli, 2004) map BPEL into different Process Algebra; (Ouyang, Aalst, Breutel, Dumas, Hofstede, & Verbeek, 2005; Schmidt & Stahl, 2004) present different semantics of BEPL in Petri nets; (Fisteus, Fern´andez, & Kloos, 2004; Foster, Uchitel, Magee, & Kramer, 2003; Fu, Bultan, & Su, 2004) use automata to model BPEL for verification. These models have similar expression power and similar reasoning or computing techniques.

Web service composition techniques are relevant to this article because they generate new Web service processes. AI planning methods are the most commonly used techniques for Web service composition. (Narayanan & McIlraith, 2002) starts from DAML-S descriptions and automatically transforms them into Petri nets. Other works, as (Berardi, Calvanese, de Giacomo, Lenzerini, & Mecella, 2003; Lazovik, Aiello, & Papazoglou, 2003; Pistore, Traverso, Bertoli, & Marconi, 2005), rely on transition rules systems. (Rao & Su, 2004) is a survey article on automated Web service composition methods. Re-planning is relevant to this article because it can be used to modify the Web service processes for fault recovery. (Canfora, Penta, Esposito, & Willani, 2005) presents a re-planning technique based on slicing techniques. When the estimated QoS metrics are not satisfied, the re-planning selects other Web services to replace the ones in the process.

CONCLUSION

Web services are the emergent technology for business process integration. A business process can be composed of distributed Web services. The interactions among the Web services are based on message passing. To identify the Web services that are responsible for a failed business process is important for e-business applications. Existing throw-and-catch fault handling mechanism is an empirical mechanism that does not provide sound and complete diagnosis. In this article, we developed a monitoring and diagnosis mechanism based on solid theories in MBD. Automata are used to give a formal modeling of Web service processes described in BPEL. We adapted the existing MBD techniques for DES to diagnose Web service processes. Web service processes have all the features of software systems and do not appear to function abnormally until an exception is thrown and they are stopped, which makes the diagnosis principle different from diagnosing physical systems. The approach developed here reconstructs execution trajectories based on the model of the process and the observations from the execution. The variable dependency relations are utilized to deduce the actual Web services within a trajectory responsible for the thrown exceptions. The approach is sound and complete in the context of modeled behavior. A BPEL engine can be extended for the monitoring and diagnosis approach developed in this article.

ENDNOTES

1 In diagnosis concept, symptom is an observed abnormal behavior, while fault is the original cause of a symptom. For example, an alarm from a smoke detector is a symptom. The two possible faults, a fire or a faulty smoke detector, are the causes of the symptom.

2 $F(c_i)$ is a specific fault mode. When we do not know a specific fault mode, we use $ab(c_i)$ to represent c_i is faulty.

3 When a Web service engine supports multiple instances of a process, different instances are identified with a process ID. Therefore, diagnosis is based on the events for one instance of the process.

4 Sometimes, the exception returns the information about the part *A.InVar.part* is faulty. Then this rule is simplified.

ABSTRACT

The World Wide Web is an important channel of information exchange in many domains, including the medical one. The ever increasing amount of freely available healthcare-related information generates, on the one hand, excellent conditions for self-education of patients as well as physicians, but on the other hand, entails substantial risks if such information is trusted irrespective of low

DOI: 10.4018/978-1-60566-218-3.ch010

competence or even bad intentions of its authors. This is why medical Web site certification, also called quality labeling, by renowned authorities is of high importance. In this respect, it recently became obvious that the labelling process could benefit from employment of Web mining and information extraction techniques, in combination with flexible methods of Web-based information management developed within the Semantic Web initiative. Achieving such synergy is the central issue in the MedIEQ project. The AQUA (Assisting Quality Assessment) system, developed within the MedIEQ project, aims to provide the infrastructure and the means to organize and support various aspects of the daily work of labelling experts.

INTRODUCTION

The number of health information websites and online services is increasing day by day. It is known that the quality of these websites is very variable and difficult to assess; we can find websites published by government institutions, consumer and scientific organizations, patients associations, personal sites, health provider institutions, commercial sites, etc. (Mayer et.al., 2005). On the other hand, patients continue to find new ways of reaching health information and more than four out of ten health information seekers say the material they find affects their decisions about their health (Eysenbach, 2000; Diaz et.al., 2002). However, it is difficult for health information consumers, such as the patients and the general public, to assess by themselves the quality of the information because they are not always familiar with the medical domains and vocabularies (Soualmia et.al., 2003).

Although there are divergent opinions about the need for certification of health websites and adoption by Internet users (HON, 2005), different organizations around the world are working on establishing standards of quality in the certification of health-related web content (Winker et.al., 2000; Kohler et.al., 2002; Curro et.al., 2004; Mayer et.al., 2005). The European Council supported an initiative within eEurope 2002 to develop a core set of "Quality Criteria for Health Related Websites" (EC, 2002). The specific aim was to specify a commonly agreed set of simple quality criteria on which Member States, as well as public and private bodies, may build upon for developing mechanisms to help improving the quality of the content provided by health-related websites. These criteria should be applied in addition to relevant Community law. As a result, a core set of quality criteria was established. These criteria may be used as a basis in the development of user guides, voluntary codes of conduct, trust marks, certification systems, or any other initiative adopted by relevant parties, at European, national, regional or organizational level.

This stress on content quality evaluation contrasts with the fact that most of the current Web is still based on HTML, which only specifies how to layout the content of a web page addressing human readers. HTML as such cannot be exploited efficiently by information retrieval techniques in order to provide visitors with additional information on the websites' content. This "current web" must evolve in the next years, from a repository of human-understandable information, to a global knowledge repository, where information should be machine-readable and processable, enabling the use of advanced knowledge management technologies (Eysenbach, 2003). This change is based on the exploitation of *semantic web* technologies. The Semantic Web is "an extension of the current web in which information is given a well-defined meaning, better enabling computers and people to work in cooperation" based on metadata (i.e. semantic annotations of the web content) (Berners-Lee et.al., 2001). These metadata can be expressed in different ways using the Resource Description Framework (RDF) language. RDF is the key technology behind the Semantic Web, providing a means of expressing data on the web in a structured way that can be processed by machines.

In order for the medical quality labelling mechanisms to be successful, they must be equipped with semantic web technologies that enable the creation of machine-processable labels as well as the automation of the labelling process. Among the key ingredients for the latter are *web crawling* techniques that allow for retrieval of new unlabelled web resources, or *web spidering and extraction* techniques that facilitate the characterization of retrieved resources and the continuous monitoring of labeled resources alerting the labelling agency in case some changes occur against the labelling criteria.

The *AQUA* (Assisting QUality Assessment) system[1], developed within the MedIEQ project[2], aims to provide the infrastructure and the means to organize and support various aspects of the daily work of labelling experts by making them computer-assisted. AQUA consists of five major components (each, in turn, incorporating several specialized tools): Web Content Collection (WCC), Information Extraction (IET), Multilingual Resources Management (MRM), Label Management environment (LAM), and Monitor Update Alert (MUA). While WCC, IET and MUA together constitute the web data analysis engine of AQUA, MRM provides them access to language-dependent medical knowledge contained in terminological resources, and LAM handles the generation, storage and retrieval of resulting labels. The user interface of AQUA allows for both entirely manual labelling and labelling based on the results of automatic analysis. In this chapter we will describe the challenges addressed and results achieved by applying the WCC and IET tools to raw web data, as well as the subsequent processes of quality label handling by LAM.

Categories and Quality of Medical Web Content: a Survey

In order to investigate what types of Medical Web Content exist, at the beginning of the project we conducted a survey on a set of Greek health-related websites, classifying them into the following categories: “government organization”, “healthcare service provider”, “media and publishers”, “patient organization / self support group”, “pharmaceutical company / retailer”, “private individual” and “scientific or professional organization”. Apart from the categorization of these websites, we also collected additional information for them in order to construct a *medical web map*. The extra fields of information were the following: “last update”, “language(s)”, “title”, “location”, “description” and “keywords” of the website but also “trust marks: are they present or not”, “trustworthiness (a first estimation on the quality of the medical content: is it reliable?)”, “advertisements: are they present or not?”.

We first collected a few thousands of URLs with the assistance of a *search engine wrapper*. The wrapper queried the Google search engine with several sets of health related keywords, in both Greek and English languages, and collected the resulting websites. From the English keywords’ results we only kept those corresponding to websites originated from Greece. On the resulting Greek URLs’ list, an automated filtering procedure was applied, where duplicates, overlapping and other irrelevant URLs were removed. 1603 URLs remained. Checking manually the remaining URLs, 723 websites were selected for having health-related content. These were then categorized according to the categories mentioned above. The *crawling software*, developed for the purposes of the project, based on machine learning and heuristic methods, extracted the machine detectable information, which is “last update”, “language(s)”, “title”, “location”, “description” and “keywords”.

Table 1. Categorization of Medical Web Content under review

Categories	*URLs*	*Percentage (%)*
Government organizations	15	2%
Healthcare service providers	211	28%
Media and publishers	64	9%
Patient organizations/ self support groups	33	5%
Pharmaceutical companies/ retailers	51	7%
Private individuals	199	28%
Scientific or professional organizations	110	15%
Universities/ research institutions	40	6%
Total	**723**	**100%**

Apparently, the 723 sites examined do not cover the totality of the Greek medical web content. However, they comprise a fair sample of that, which allowed us to make some useful observations with regard to this content.

The majority of websites belong to the *healthcare service provider* category (211 URLs) and to the *private individual* category (199 URLs). This fact reveals that in Greek medical web, the private sector is dominant (which seems reasonable), while the websites coming from the public sector like government organizations and universities/ research institutions are a minority (54 URLs). Furthermore, it is remarkable that a great portion (110 URLs) of the Greek medical web belongs to scientific/professional organizations.

We also noticed that, at the time of the survey, only three websites had a *quality seal*, namely, HON Code (HON, 2001) and all of them belong to the *scientific or professional organization* category. We could argue that the non-conformance to trust mark quality criteria characterizes the Greek medical web as a whole, which demonstrates that Greek online medical content providers are not familiar with the quality labelling aspect. Thus, the quality of the content of Greek medical websites appears to be doubtful. To support this, note that the HTML tags for "description" and "keywords" (which the crawler reads automatically), were found as either empty or containing misleading information in most Greek medical pages, while, for example, a quick look into a portion of the German medical web showed the opposite. Concluding, only few Greek medical websites conform to the biggest part of the selected criteria as to be considered of good quality.

We also conducted analogous but less elaborate studies for other 'less-spoken' languages that are involved in the MedIEQ project but not covered by the partner labelling agencies, namely Czech and Finnish. The first observations of the Czech and Finnish medical web maps seem to confirm the hypotheses formed based on the analysis of Greek websites detailed above.

Thus, the establishment of mechanisms/infrastructures for the quality certification of health related websites is quite critical. Its positive role would amount to forcing health content providers to the following directions:

- For *existing* online medical content: conform to generally accepted quality criteria defined by experts. For online medical content *planned* to be published: adapt to specific standards (presence of detailed information on the content provider, authorship information, last update, contact data, etc.).
- *High-quality* websites, already trusted by health information consumers, would

clearly boost the opinion that the web is not an advertising-oriented or dangerous space, but a powerful source of information and must be considered as such. In the same direction, the national medical sector could be motivated to develop web resources of quality, extending the usefulness of the medium and eventually attracting a larger amount of users.

The MedIEQ project aims to directly contribute to this direction.

STATE OF THE ART IN HEALTH WEB QUALITY LABELLING

Two major approaches currently exist concerning the labelling of health information in the internet: a) *filtering portals* (organizing resources in health topics and providing opinions from specialists on their content) and b) *third-party certification* (issuing certification trustmarks or seals once the content conforms to certain principles). In general, and in both approaches, the labelling process comprises three tasks that are carried out entirely or partially by most labelling agencies:

- *Identification* of new web resources: this could happen either by active web searching or on the request of the information provider, i.e. the website responsible actively asks for the review in order to get a certification seal.
- *Labelling* of the web resources: this could be done with the purpose of awarding a certification seal or in order to classify and index the web resources in a filtering portal.
- *Re-reviewing* or *monitoring* the labeled web resources: this step is necessary to identify changes or updates in the resources as well as broken links, and to verify if a resource still deserves to be awarded the certification seal.

This is the general case; eventually, any particular agency can integrate additional steps which may be necessary in its work. The two labelling agencies participating in MedIEQ, Agency for Quality in Medicine – AQuMed (http://www.aezq.de) and Web Mèdica Acreditada - WMA (http://wma.comb.es), represent the two approaches mentioned above: AQuMed maintains a filtering portal while WMA acts as a third-party certification agency.The indexing and labelling process in AQuMed consists of five steps:

1. *Inclusion of a new resource.* There are two ways through which a new resource can be identified for indexing in AQuMed database. The first one is through internet search and the second one is through a direct request from the information provider. The websites are selected according to general criteria: content, form and presentation should be serious, authorship, sponsorship and creation/update date should be clear, and only websites without commercial interest should be indexed.
2. *Website classification.* Previously unlabelled websites are classified into four groups: treatment information, background information, medical associations/scientific organizations and self-help/counseling organizations. Only the sites with treatment information proceed to the next step.
3. *Evaluation.* Sites with treatment information are evaluated using the DISCERN (DISCERN, 2008) and Check-In (Sanger, 2004) instruments. DISCERN is a well-known user guidance instrument, and Check-In was developed by AQuMed in collaboration with the "Patient Forum" of the German Medical Association. Check-In is based on DISCERN and the AGREE (AGREE, 2004)

instrument for critical evaluation of medical guidelines.

4. *Confirmation.* The database administrator has to confirm the result of the evaluation. It can be modified, erased, or simply confirmed.
5. *Feedback to the information provider.* AQuMed sends an e-mail with the result of the evaluation in the case of sites with treatment information and with the information about the admission into the AQuMed database in the case of other categories.

AQuMed's database is periodically populated through new internet searches and is regularly examined for broken links. The evaluated web resources are also periodically re-reviewed in order to identify changes against the criteria or other updates.Similarly, the complete certification process in WMA consists of the following four steps:

1. The person in charge of a website sends a (voluntary) request to WMA in order to initiate the process. Using the online application form, the interested party provides certain information to WMA and has the chance to auto-check the WMA criteria based on the Code of Conduct and the Ethical Code;
2. The WMA Standing Committee assesses the website based on the WMA criteria (medical authorship, updating, web accessibility, rules in virtual consultation, etc.), and issues recommendations;
3. WMA sends a report to the person in charge who implements the recommendations;
4. When the recommendations have been implemented, it is possible to obtain the seal of approval. In such a case, WMA sends an HTML seal code to be posted on the accredited website. In addition, WMA includes the site's name and URL to the index of accredited websites and an RDF file is generated.

EXPERIMENTAL COLLECTION OF LABELLING CRITERIA

In the MedIEQ project we decided to develop a representative collection of *labelling criteria*, which would reflect the needs of the *labelling agencies* involved in the project consortium and at the same time provide an adequate proof of concept for our general methodology for computer-assisted labelling. It is important to stress that the methodology and software tools are to a large degree independent of the concrete criteria and thus could be easily adapted to different criteria used by various agencies. Such adaptation is also eased by the fact that the criteria specification was also influenced by the analysis of criteria used by other organizations such as HON, and thus has significant overlap with them.

The set of labelling criteria used in MedIEQ (36 in total, organized in 10 different categories) is shown in Table 2. For each of these criteria, the AQUA system aims to identify and extract relevant information to be proposed to the expert (i.e. automatically provide information otherwise searched for manually within the site). The expert can accept or modify AQUA's suggestions and generate a quality label on the fly.

THE AQUA SYSTEM OVERVIEW

Development Objectives

Taking into account WMA and AQuMed approaches, the AQUA tool (Stamatakis et. al., 2007) was designed to support the main tasks in their labelling processes, more specifically:

1. Identification of unlabelled resources having health-related content
2. Visit and review of the identified resources
3. Generation of content labels for the reviewed resources

Table 2. The set of criteria examined in MedIEQ

ID	Criterion Name	Description
1. Resource Defining Information		
1.1	Resource URI	Includes information identifying/describing the resource. Concerning the resource URI: a) whether the resource's URI is valid or not and b) in case it redirects to external domains, are these domains between those specified when the resource was added? The rest is information like the resource's last update, its title and the language(s) in which content is provided.
1.2	Resource title	
1.3	Resource last update	
1.4	Resource language(s)	
2. Ownership / Creatorship		
2.1	Organization name(s) (owner)	The user should know who is behind the resource in order to judge by himself the credibility of the provided information. Therefore, information like the name(s) of the organization(s) providing the information and the type of this(these) organization(s) should be available. At the same time, the name(s), title(s) (e.g. MD, PhD, Dr, etc.) and contact details of website responsible(s), to contact in case of questions on health related issues, as well as the name(s) and contact details of the webmaster(s) should be available.
2.2	Organization type(s) (owner)	
2.3	Responsible name(s)	
2.4	Responsible title(s)	
2.5	Responsible(s) contact details	
2.6	Webmaster name(s)	
2.7	Webmaster(s) contact details	
3. Purpose / mission		
3.1	Purpose / mission of the resource provided	It has to be clear for the user which is the goal and motivation of the provided information and for what kind of users it was created e.g. adults, children, people with diabetes, etc.
3.2	Purpose / mission of the owner(s) provided	
3.3	Target / intended audience(s)	
3.4	Statement declaring limitation of the provided information	
4. Topics / Keywords		
4.1	Topics / Keywords (UMLS)	Mapping of the resource's content to concepts from the UMLS Metathesaurus.
5. Virtual consultation		
5.1	VC service available	A virtual consultation (VC) service is an online service allowing the user to ask questions and/or send/upload information on health related issues asking for advice. The name(s) and details of the person(s) responsible(s) for this service should also be clearly mentioned. Moreover, a declaration that VC is only a supporting means that cannot replace a personal consultation with a physician should be provided.
5.2	VC responsible name(s)	
5.3	VC responsible(s) contact details	
5.4	Statement declaring limitation of the VC service	
6. Funding / Advertising		

Table 2. continued

ID	*Criterion Name*	*Description*
6.1	Statement declaring sources of funding (sponsors, advertisers, etc.)	Health web resources should disclose possible conflicts of interest. For this reason it is important to know how and by whom a web resource is funded. If there are any sponsors, it has to be clear who they are. Furthermore, it should be stated that sponsors do not have any influence on the content. Additionally, it has to be known whether the web resource hosts or not advertising material in whatever format. In case that happens, such material should be clearly distinguished from informative material. Furthermore, information on resource's policy with regard to advertising must be easily accessible and clear.
6.2	Name(s) of funding (sponsoring) organization(s)	
6.3	Statement declaring limitation of influence of sponsors on content	
6.4	Advertising present	
6.5	Are advertisements clearly separated from editorial content?	
6.6	Policy with regard to advertisement	
7. Other Seal or Recommendation		
7.1	Other seal(s) present	Are there other seals identified in the resource? Indicates that the resource already conforms to other, known quality criteria. Identifiers for other seals: a) Real seals: WMA, HONcode, pWMC, URAC, eHealth TRUST-E, AFGIS, b) Filtering health portals (a resource is recommended by): AQUMED, Intute, WHO ("Vaccine Safety Net")
7.2	Which other seal(s)?	
8. Information Supporting Scientific Content		
8.1	References, bibliography (with links to literature)	Regarding the provided specialized health information (scientific parts of the resource) it is relevant to know if it is based on scientific books, medical journal articles, etc. For this, scientific articles or documents should include a references or bibliography section. Additionally, it is important to know if such information is up-to-date (publication and last modification dates are required) and who is the author of such content (author(s) name(s) and contact details are required for pages/documents providing scientific information).
8.2	Publication / creation date	
8.3	Last revision / modification date	
8.4	Author name(s)	
8.5	Author(s) contact details	
8.6	Editorial policy	
9. Confidentiality / privacy policy		
9.1	Explanation on how personal data (visitor coordinates, e-mail messages, etc.) is handled	Internet users are much concerned about protection of their privacy and personal data. For this reason the resource should provide a confidentiality/privacy policy ensuring that personal data (visitor coordinates, e-mail messages, etc.) is safely handled, describing how these data are handled.
10. Accessibility		
10.1	Accessibility level	The resource is examined upon various accessibility criteria and information on its accessibility level (whether the resource is of level A, AA or AAA) is deduced.

4. Monitoring the labeled resources

Compared to other approaches that partially address the assessment process (Griffiths et. al., 2005; Wang & Liu, 2006), the AQUA system is an integrated solution. AQUA aims to provide the infrastructure and the means to organize and support various aspects of the daily work of labelling experts by making them computer-assisted. The steps towards this objective are the following:

- **Step 1:** Creating machine readable labels by:
  - Adopting the use of the RDF model (W3C, 2004) for producing machine-readable content labels; at the current stage, the RDF-CL model (W3C, 2005) is used. In the final version of AQUA, another model called POWDER, introduced by the recently initiated W3C Protocol for Web Description Resources (POWDER) working group (W3C, 2007), will be supported.
  - Creating a vocabulary of criteria, consolidating on existing ones from various Labelling Agencies; this vocabulary is used in the machine readable RDF labels.
  - Developing a label management environment allowing experts to generate, update and compare content labels.
- **Step 2:** Automating parts of the labelling process by:
  - Helping in the identification of unlabelled resources.
  - Extracting from these resources information relative to specific criteria.
  - Generating content labels from the extracted information.
  - Facilitating the monitoring of already labeled resources.
- **Step 3:** Putting everything together; AQUA is implemented as a large-scale, enterprise-level, web application having the following three tiers:
  - The user tier, including the user interfaces for the labelling expert and the system administrator.
  - The application tier where all applications run.
  - The storage tier consisting of the MedIEQ file repository and the MedIEQ database.

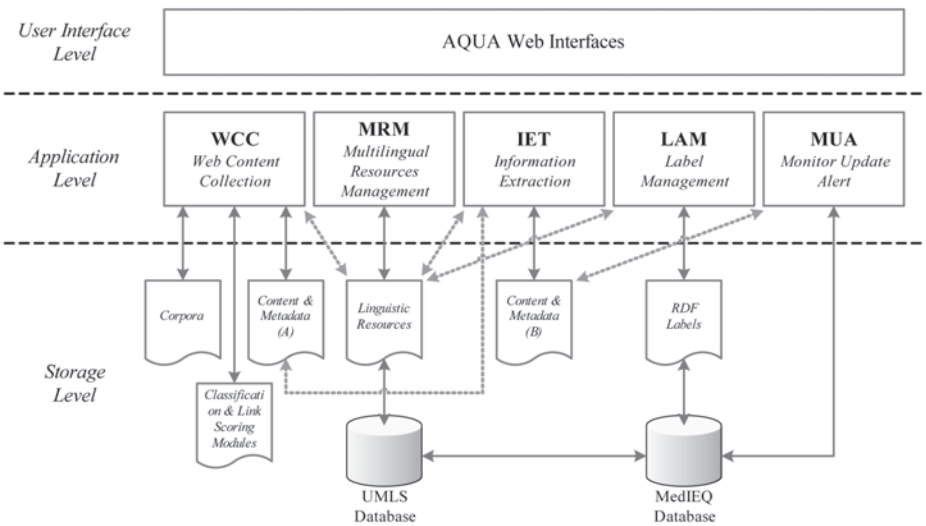
System Architecture

AQUA addresses a complex task. However, various design and implementation decisions helped MedIEQ partners keep AQUA extensible and easy to maintain. The main characteristics of its implementation include:

a. Open architecture
b. Accepted standards adopted in its design and deployment
c. Character of large-scale, enterprise-level web application
d. Internationalization support

AQUA incorporates several subsystems (see the application level in Figure 1) and functionalities for the labelling expert. The *Web Content Collection* (WCC) component identifies, classifies and collects online content relative to the criteria proposed by the labelling agencies participating in the project. The *Information Extraction Toolkit* (IET) analyses the web content collected by WCC and extracts attributes for MedIEQ-compatible content labels. The *Label Management* (LAM) component generates, validates, modifies and compares the content labels based on the schema proposed by MedIEQ. The *Multilingual Resources Management* (MRM) gives access to health-related multilingual resources; input from such resources is needed in specific parts of the WCC, IET and LAM toolkits. Finally, *Monitor-Update-Alert* (MUA) handles auxiliary but important jobs

Figure 1. Architecture of the AQUA system



like the configuration of monitoring tasks, the MedIEQ database updates, or the alerts to labelling experts when important differences occur during the monitoring of existing content labels.

While the first prototype, made operational in autumn 2007, only addresses the certification of new resources and covers two languages (English and Spanish), the full version of the system will also enable monitoring of already labeled resources and will cover 7 languages in total.

Figure 1 shows all the possible data flows in AQUA (dashed arrows): a) From WCC to IET: pages collected by WCC, once undergone a first-level extraction by WCC (extraction of metadata 1), are then forwarded to IET for further processing (extraction of metadata 2); b) From IET to MUA: MUA takes all metadata collected by both WCC and IET and updates the MedIEQ database; c) From MRM to WCC, IET, LAM: custom vocabularies, generated by the MedIEQ users through MRM interface, can be accessed from other toolkits (WCC, IET, LAM), where the user may need them.

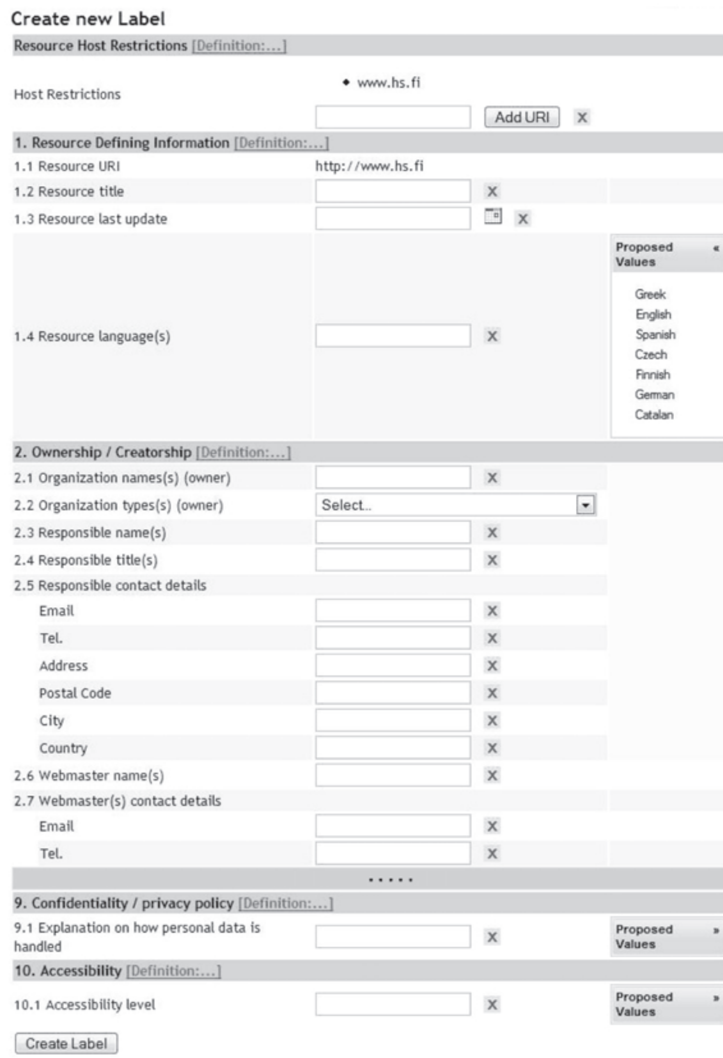
The following two sections are devoted to a more detailed description of AQUA, namely of its (manual) label management components and of its automated labelling support components.

AQUA LAM COMPONENT: CREATING MACHINE-READABLE LABELS

Representation Formalism for Machine-Readable Labels

To make content labels machine-readable the use of the RDF model is adopted. At the current stage, the RDF-CL model is used. The RDF-CL model was issued by the EC-funded project Quality Assistance and Content Description (QUATRO) (www.quatro-project.org); it is currently being refined by the W3C Protocol for Web Description Resources (POWDER) working group (W3C, 2007). POWDER is expected to be completed before the end of the

Figure 2. The AQUA label management environment (LAM) interface



MedIEQ project and the plan is to use it in the final version of AQUA.

User Interaction with the Label Management Environment

The *label management* interface and associated tools, together called LAM, allows experts to generate, update and compare content labels. From within the LAM user interface the user is able to a) generate new RDF labels from information automatically extracted by other AQUA tools, b) manually fill the relevant fields and generate new RDF labels, c) edit and update existing RDF labels, and d) compare RDF labels among themselves.

The user interface to generate/edit a label is a *web form* (see Figure 2) with input boxes, single and multiple select boxes, links and buttons. It is split into two distinct areas. The first part lets the user *constrain* the application of the label to certain hosts by explicitly declaring the host URIs or by adding regular expressions that properly identify them. Multiple hosts can be defined. Regular expressions for more fine-grained addressing can be defined as well. These definitions can be combined via the union and intersection operators and thus create rules that link different parts of a web resource with different labels.

The second part is where the *label properties* are assigned *values*. The label properties are the actual descriptors of a web resource, mapping the labelling criteria. A set of label descriptors can be linked with a set of host restrictions defined in the first part. Related properties are grouped to make the user filling them easier.

Once the user has filled the label metadata, restrictions and properties, s/he can *save* the label. There is a notification field that alerts the user if the label already exists in the system, and its changes are tracked by the AQUA version control system. In this case the user can save the label as a *revision* of an existing label. If the label is new, the user just selects to save the label. In both cases the user has the option to download an RDF/XML serialized form of the label. This serialized label can be assigned to the web resource by the site webmaster.

AQUA WCC+IET: AUTOMATING PARTS OF THE LABELLING PROCESS

Locating Unlabeled Web Resources

The AQUA *crawling* mechanism is part of the *web content collection* environment (WCC) (Stamatakis et. al., 2007). Its AQUA interface is shown in Figure 3. The Crawler searches the Web for health-related content that does not have a content label yet (at least not a label found in MedIEQ

Figure 3. Configuring the MedIEQ Crawler from the AQUA interface

records). It is a meta-search engine that exploits results returned from known search engines and directory listings from known Web directories. All collected URLs from all sources are merged and filtered, and a pre-final URLs list is returned. The merging / filtering process: a) removes possible duplicates, b) ignores sub-paths of URLs already in list, and c) removes URLs already having a content label (the Crawler consults the MedIEQ database for this).

The crawling process becomes even more focused with the aid of a *content classifier*, inductively trained to distinguish health content from non-health content. This classification component visits every URL from the merged / filtered pre-final URL list and checks its contents, thus filtering out some more entries.

The current version of the AQUA Crawler queries Google and Yahoo! *search engines* (with terms proposed by the user) and explores Web directories (again proposed by the user). By merely using general-purpose search engines, the Crawler inevitably inherits their shortcomings. Therefore, aiming to further enhance our Crawler, we also include two search mechanisms specialized to the *health domain*: one provided by HON (www.hon.ch) and another by Intute's Health and Life Sciences branch (www.intute.ac.uk). The Crawler interface is shown in Figure 3.

Browsing Medical Knowledge Sources

One of the main requirements when working with medical web resources, is to identify and classify them based on standardized medical terms. Such terms (knowledge sources) have been globally defined by the Unified Medical Language System (UMLS) (www.nlm.nih.gov/ research/ umls/). UMLS provides a wide set of linguistic health resources, well maintained and up-to-date, containing health concepts and relations between concepts and between resources.AQUA incorporates a module called Multilingual Resources Management Toolkit (MRM) that aims to support labelling experts in:

- Easily accessing and browsing selected "knowledge sources" form the variety that UMLS provides
- Creating new, custom resources, to better support the labelling process

MRM is an environment from which linguistic resources, either UMLS-supported or not (custom or user generated) in different languages can be managed. MRM provides a user-friendly environment for accessing and managing both UMLS "knowledge sources" and custom resources (see Figure 4).

Spidering the Website

While the Crawler proceeds from the initial user's content collection requirement to the identification of a relevant website as a whole, the *Spider*, in turn, examines individual pages of the site. The sites whose URLs are obtained from the Crawler are processed by the Spider one-by-one in several independent threads. Unreachable sites/pages are revisited in next run.

Since not all the pages of a web site are interesting for the labelling process, the Spider utilizes a content classification component that consists of a number of *classification modules* (statistical and heuristic ones). These modules decide which pages contain interesting information. Each of them relies on a different classification method according to the classification problem on which it is applied. Pages identified as belonging to classes relevant to the labelling criteria are stored locally in order to be exploited by the Information Extraction subsystem.

One of the main classification modules of the Spider is the "UMLS/MeSH categoriser", called POKA. POKA (http://www.seco.tkk.fi/tools/poka/) is a tool for automatic extraction of ontological resources (RDF, OWL, SKOS) from text

documents. In the MedIEQ framework, POKA is used to find relations between medical web content and medical vocabularies such as MeSH to facilitate categorization of web resources. The POKA system is used as a component of the web spidering tool where the spider traverses health web sites by gathering internal links and visiting the corresponding web pages one by one. POKA is then harnessed to find medical terminology inside these pages by matching content with the MeSH vocabulary.

Extracting Information Relative to Criteria

MedIEQ continues and builds upon the work of previous projects in the area of *information extraction* (IE) (Karkaletsis et.al. 2004; Rainbow, 2005; Labsky & Svatek, 2006). The AQUA IE toolkit (IET) employs a set of components responsible for the extraction of elementary information items found in each document and for the integration of these items into a set of semantically meaningful objects called *instances*. An instance (of certain general class) can be for example the set of contact information about a health provider or the set of bibliographic information about a scholarly resource referred to on the website.

The core IE engine currently used within IET is the *Ex* system (Labsky et al., 2007), which relies on combination of so-called *extraction ontologies* with exploiting local *HTML formatting regularities* and the option of embedding *trainable classifiers* to perform selected extraction subtasks. IET is built as a generic information extraction toolkit that supports changes and additions to the utilized labelling schemes. In this way, IET can also be used for IE using third-party labelling schemes and within other domains.

Monitoring of Already Described Resources

Another part of AQUA, called MUA (from Monitor-Update-Alert), handles problems such as the *configuration* of *monitoring tasks*, the necessary MedIEQ *repository updates* and the *alerts* to labelling experts when important differences (relative to the quality criteria) occur during the monitoring of previously labeled sites. MUA thus extends the functionality of the content collection and extraction toolkits by shifting from a one-shot scenario to that of continuous monitoring.

MUA is currently in its design phase. Fully functional implementation is envisaged in the late phase of the MedIEQ project (mid-2008).

PRELIMINARY EVALUATION OF AQUA

Locating Unlabeled Web Resources

In this section, we summarize evaluation results on Crawler's content classification component. For this evaluation, we used an English corpus, consisting of 1976 pages (944 positive & 1032 negative samples), all manually annotated. Three different classifiers have been tested (SMO, Naïve Bayes and Flexible Bayes). All 1-grams, 2-grams and 3-grams were produced and the best of them according to information gain were selected (see Table 3). Best performance was achieved with 1-grams and HTML tags removed.

The relatively low performance of the content classifiers is justified by the fact that it is difficult, even for humans, in various cases to assess whether a website has health-related content or not.

Spidering the Website

The classification mechanism our Spider exploits has been examined using statistical classification techniques, for the criteria listed in Table 4. In addition, for the last criterion, a method based on heuristic detection was examined.

Several learning schemes, decision trees, naive Bayes and supported vector machines (SMO) were tested. The performance of the SMO classifier, which provides the best results, is presented in Table 5. As expected, the most difficult criterion for classification purposes is the target audience, being a highly subjective one.

Extracting Information Relative to Criteria

Table 6 shows preliminary results for extraction of *contact information*. Data sets were collected through website crawling and spidering, contact pages were identified and manually annotated for English (109 HTML pages), Spanish (200) and Czech (108). The collections contained roughly 7000, 5000 and 11000 named entities, respectively. The *contact extraction* ontologies (one per language with shared common parts) were developed based on seeing 30 randomly chosen documents from each dataset and evaluated using

the remaining documents. Extraction ontologies utilize nested regular patterns at word, character and HTML tag level. They also refer to gazetteers such as lists of city names, common first names and surnames. Each ontology contained about 100 textual patterns for the context and content of attributes and also for the single extracted ’contact’ class, attribute length and data type constraints and several axioms. For the results below we did not exploit trainable classifiers; their meaningful combination with the manually authored extraction knowledge is still work-in-progress, and when applied standalone, their results were so far slightly inferior to those achieved via extraction ontologies. We attribute this observation to small amount and large heterogeneity of training data.

The effort spent on developing and tuning the ontologies was about 2-3 person-weeks for the initial, English ontology, and 1-2 person weeks for its customization to Spanish and Czech. In the strict mode of evaluation, only exact matches are considered to be successfully extracted. In the loose mode, partial credit is also given to incomplete or overflown matches; e.g. extracting ’John Newman’ where ’John Newman Jr.’ was supposed to be extracted will count as a 66% match (based on overlapping word counts). Table 6 shows results in ‘strict/loose’ order. Some of the performance numbers below may be impacted by a relatively low inter-annotator agreement (English and Spanish datasets are still being cleaned to remove inconsistencies).

AQUA Usability Evaluation

The 1st AQUA prototype was also evaluated by the labelling organizations participating in the MEDIEQ project (namely, WMA and AQUMED). The primary goal of this evaluation was to conclude with a functional prototype that has the potential to be fully integrated within the day-to-day activities of a labelling organization. To this end, a

parallel technical improvement action took place, refining given functionalities. The main objective of the extra technical improvement action was to enhance the overall system workflow, so as to better match the day-to-day practice. The specifications for these technical refinements were given by an iterative feedback process with the MedIEQ labelling organizations, during the evaluation. It must be noted that the current interim version of AQUA was well received by both labelling organizations participating in the Usability Evaluation testing, and that they expressed their confidence that AQUA will be fully integrated within their day-to-day labelling activities.

CONCLUDING REMARKS

Other attempts to automatically assess health information in the internet exist but address the assessment process only partially. The Automated Quality Assessment procedure (AQA) (Griffiths et. al., 2005) ranks depression websites merely according to their evidence-based quality. The Automatic Indicator Detection Tool (AIDT), presented in a recent study (Wang & Liu, 2006), is suggested as a complementary instrument for the assessment of health information quality. AIDT is evaluated upon the automatic detection of pre-defined indicators that correspond to a number of technical quality criteria. However, AIDT focuses on a narrow scope of extraction techniques only, and does not address the assessment process as a whole. In contrast, the AQUA approach seems to be unique in covering the whole workflow of labelling agencies and employing a comprehensive and flexible collection of automated tools.

Assessing the quality of health-related information published on the internet is a task with great importance for the quality of the healthcare itself, due to a large proportion of patients as well as medical practitioners nowadays using the internet as a high-coverage information resource. It is at the same time a complex task as it has to examine the conjunction of a number of different aspects. Various initiatives around the world have attempted to codify these aspects into criteria, principles, codes of conduct, etc. Health specialists review online health resources and label them, either by issuing certification trustmarks or by including them in a thematic health portal. However this work can be proven quite tedious even for experienced users. Additionally, as it currently relies on manual effort, the labelling process is very time-consuming. Instruments to assist certain parts of the work exist; they however focus on specific problems only and none of them addresses the assessment process as a whole. In this context, efforts such as the MedIEQ project will bring wide reusability to content labels in the health domain by giving them machine-readable semantics and by providing services, such as those of the AQUA system, for creating and exploiting these machine-readable labels.

From the knowledge technology research viewpoint, the added value of MedIEQ is in employing existing technologies in a novel application: the automation of the labelling process in health-related web content. These technologies are *semantic web* technologies for describing web resources and *web search* (crawling and spidering) *and mining* (classification and information extraction) technologies for collecting domain-specific web content and extracting information from it. Experimental results for the mining components, investigating the performance of different inductive-learning-based as well as knowledge-engineering-based methods, are promising.

KEY TERMS AND DEFINITIONS

Crawling: A web crawler is a program or automated script which browses the World Wide Web in a methodical, automated manner. This process is called web crawling. Web crawlers are mainly used to create a copy of all the visited pages for later processing.

Information Extraction: Automatic assignment of meaning to elementary textual entities and possibly more complex structured objects.

Metadata: Data that describes information about either online or offline data. Information that characterizes the who, what, where, and how related to data collection. Often, the information refers to special tagged fields in a document that provide information about the document to search engines and other computer applications. Web pages often include metadata in the form of meta tags. Description and keywords meta tags are commonly used to describe the Web page's content. Most search engines use this data when adding pages to their search index.

Resource Description Framework (RDF): Resource Description Framework (RDF) is a family of World Wide Web Consortium (W3C) specifications originally designed as a metadata data model, but which has come to be used as a general method of modeling information through a variety of syntax formats. The RDF metadata model is based upon the idea of making statements about Web resources in the form of subject-predicate-object expressions, called triples in RDF terminology. The subject denotes the resource, and the predicate denotes traits or aspects of the resource and expresses a relationship between the subject and the object.

Semantic Web: The Semantic Web is an evolving extension of the World Wide Web in which the semantics of information and services on the web is defined, making it possible for the web to understand and satisfy the requests of people and machines to use the web content. It derives from W3C director Tim Berners-Lee's vision of the Web as a universal medium for data, information, and knowledge exchange. At its core, the semantic web comprises a set of design principles, collaborative working groups, and a variety of enabling technologies. Some elements of the semantic web are expressed as prospective future possibilities that have yet to be implemented or realized. Other elements of the semantic web are expressed in formal specifications.

Spidering: A web spider is a complementary mechanism/tool to a web crawler. Web crawlers are mainly used to create a copy of all the visited pages for later processing, whereas, web spiders are used to gather specific types of information from Web pages. Many sites, in particular search engines, use spidering as a means of providing up-to-date data.

Web Mining: Web mining is the application of data mining techniques to discover patterns from the Web. According to analysis targets, web mining can be divided into three different types, which are Web usage mining, Web content mining and Web structure mining. Web usage mining is the application that uses data mining to analyse and discover interesting patterns of user's usage data on the web. Web content mining is the process to discover useful information from the content of a web page. The type of the web content may consist of text, image, audio or video data in the web. Web structure mining is the process of using graph theory to analyse the node and connection structure of a web site.

Chapter 7.10
User Facing Web Services in Portals

Jana Polgar
NextDigital, Australia

ABSTRACT

In SOA framework, Portal applications aggregate and render information from multiple sources in easily consumable format to the end users. Web services seem to dominate the integration efforts in SOA. Traditional data-oriented web services require portlet applications to provide specific presentation logic and the communication interface for each web service. This approach is not well suited to dynamic SOA based integration of business processes and content. WSRP 2.0 aim at solving the problem and providing the framework for easy aggregation of presentation services. Is not practical to publish portlets locally if the organisation wishes to publish their portlets as web services to allow their business partners using these services in their portals. UDDI extension for WSRP enables the discovery and access to user facing web services while eliminating the need to design local user facing portlets. Most importantly, the remote portlets can be updated by the web service providers from their own servers.

VISION FOR USER-FACING PORTLETS

Web services introduced the means for integrating and sharing business processes via the Internet. WSRP (WSRP specification version 1 (2003)) goal is to extend the integration further by providing framework for sharing web service presentation components. WSRP specification formulated a standard protocol which enables all content and application providers to create web services, generate their presentation faces as HTML fragments and offer them to the consumers to be plugged into their local portals.

Portals and portlets (JSR 168 (2005)) provide specific presentation logic to aggregate data from multiple sources which could be legacy systems, Enterprise Information Systems (EIS), local or remote web services, or EIS with exposed web service interfaces. The first draft of JSR 286 (JSR 286 (2008) brings new features to the Java portlets capabilities introduced by WSRP 2.0 (WSRP Specification version 2.0 (2008)). JSR 286 new features include:

- Interportlet communication: coordination between portlets and allow building composite applications based on portlet components;
- Shared render parameters enable to specify which render parameters they can share with other portlets;
- Resource serving feature enables portlets to serve resources within the portlet context;
- Frameworks for better support for JSF and Struts
- Alignment with WSRP 2.0
- Better user experience using AJAX patterns
- Portlet filters to selectively define the portlets which can transform the content of portlet requests and responses on the fly.

The WSRP specification is intended for presentation-oriented web services, user-facing web services that can be easily integrated with portals. They let businesses provide content or applications without requiring any manual content or application-specific adaptation by portal presentation logic. It is envisaged that in the near future portals will easily aggregate WSRP services without any programming effort. The only effort required is the actual deployment of remote portlets in the local portal server (Hepper, S and Hesmer, S. (2003)). We are not taking into account the effort needed for the "implementation", that is the design of the portal page which is needed in any case.

The WSRP specification (WSRP specification version 1 (2003) and WSRP 2.0 are the effort of the working group at OASIS (http://www.oasis-open.org/committees/wsrp). It aims to provide a set of options for aggregating user-facing web services (remote portlets) from multiple remote web services within one portal application. WSRP standard has been conceived for implementing simple services. The developer of the portlet provides the markup fragments to display web service data. The current version allows for more complex services that require consumer registration, support complex user interaction, and operate on transient and persistent state maintained by the service provider. Before looking at the functionality of WSRP, note that what WSRP refers to as a portlet is the combination of a portlet implementation and any configuration data that supports the implementation. WSRP 2.0 (WSRP Specification version 2.0 (2008) is closely aligned with the JSR286 thus providing the framework for publishing JSR286 portlets as web services.

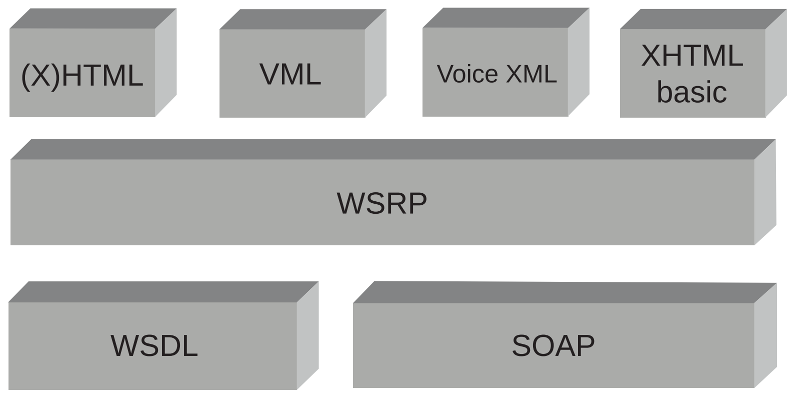
WSRP AND WSRP RELATED STANDARDS

WSRP defines the notion of valid fragments of markup based on the existing markup languages such as HTML, (X)HTML, VoiceXML, cHTML, etc (Figure 1). For markup languages that support CSS (Cascading Style Sheet) style definitions, WSRP also defines a set of standard CSS class names to allow portlets to generate markup using styles that are provided by WSRP compliant portals such that the markup assumes the look and feel of the consuming portal.

WSRP is fully integrated with the context of the web services standards stack. It uses WSDL additional elements to formally describe the WSRP service interfaces and requires that at least SOAP binding be available for invocations of WSRP services. WSRP also defines the roles of web service *producers* and *consumers*. Both *producers* and *consumers* use a standard protocol to provide and consume web services for user facing portlets. The WSRP specification requires that every *producer* implement two required interfaces, and allows optional implementation of two others:

1. **Service Description Interface (required):** This interface allows a WSRP *producer* to advertise services and its capabilities to

Figure 1. WSRP related standards



consumers. A WSRP *consumer* can use this interface to query a *producer* to discover what user-facing services the *producer* offers.

2. **Markup Interface (required):** This interface allows a *consumer* to interact with a remotely running portlet supplied by the *producer*.
3. **Registration Interface (optional):** This interface serves as a mechanism for opening a dialogue between the *producer* and *consumer* so that they can exchange information about each others' technical capabilities.
4. **Portlet Management Interface (optional):** This interface gives the *consumer* control over the life cycle methods of the remote portlet.

URL generation concept: To support user interaction, all the URLs embedded in the markup fragment returned by the remote *producer* service must point back to the *consumer* application. Therefore, the *consumer* needs to send a URL template as part of the invocation of the `getMarkup()` method. For example, the consumer may send the URL template with two variables: `navigationState` and `sessionID`:.

```
http://neptune.monash.edu.au/myApp?ns={navigationState}&si={sessionID}
```

The *producer* responsibility is to generate a markup fragment in which all the interaction URLs must point back to the *consumer*. The *producer* generates a link pointing to the URL replacing the template variables `navigationState` and `sessionID` with concrete values:

```
http://neptune.monash.edu.au/myApp?ns=page2&si=4AHH55A
```

Alternatively, the predetermined pattern allows the *producer* to create URLs that is compliant with this pattern. The *consumer* then parses the markup and rewrites variable parts of URL to point back to the application.

ROLE OF PRODUCERS AND CONSUMERS

WSRP is a protocol in which the interaction always occurs between two web applications or web services. The *consumer* application acts as a client to another application called *producer*. The *producer* provides end-user-facing (also called presentation services) web services in the form of remote portlets. These remote portlets are aggregated into the *consumer's* portal page in the same way as local portlets.

Let's start with comparing WSRP with a web services application. The web based application *consumer* uses HTTP, SOAP and browsers to interact with remote servers hosting web services. In response they receive web service raw **data** needed to create the markup (typically HTML or HTML form). The input data are posted by submitting the form via a browser.

HTTP protocol is also utilized with WSRP. *Consumers* can be seen as intermediaries that communicate with the WSRP *producers. Consumers* gather and aggregate the **markup** delivered by local as well as remote portlets created by the *producers* into a portal page. This portal page is then delivered over SOAP and HTTP to the client machine (PC or a workstation). The *consumer* is responsible for most of the interactions with the remote systems, ensuring user privacy and meeting the security concerns with regard to the processing information flow.

In a sense of additional capabilities, today's *consumers* of WSRP are more sophisticated than simple web service clients:

1. *Consumer* aggregates multiple interface components (local and remote portlets) into a single page. In addition, features like personalization, customization and security are also available for remote portlets;
2. The aggregation into a single page is not straightforward since it involves applying *consumer*-specific page layouts, style and skins to meet the end-user requirements. Therefore, the *consumer* must have knowledge of "presenting" related features in remote portlets to apply customization and rendering.
3. The *consumer* can aggregate content produced by portlets running on remote machines that use different programming environments, like J2EE and .NET.
4. *Consumers* are able to deal with remotely managed sessions and persistent states of WSRP web services.

The *producer* is responsible for publishing the service and portlet capabilities descriptions in some directory e.g. UDDI. It allows the *consumer* to find the service and integrate it into portal. The purpose of the portlet capabilities description is to inform the *consumer* about features each portlet offers. *Producer's* major responsibilities are listed below:

5. *Producers* are capable of hosting portlets (they can be thought of as portlet containers). Portlets generate markup and process interactions with that markup;
6. *Producers* render markup fragments which contains web service data.;
7. *Producers* process user interaction requests; and
8. *Producers* provide interfaces for self description, and portlet management.

The *consumer* can optionally *register* with the *producer.* The *producer* is responsible for specifying whether the registration is required. Typical registration contains two types of data: *capabilities* (for example, window states and modes the *producer's* remote portlets support), and *registration properties* (required data prescribed in the service description). Upon successful registration, the *consumer* receives a unique registration handle. This handle allows all portlets to be scoped to fit to the local portal. Optionally, the *consumer* may provide the credentials to the *producer.*

Portlet management is an optional interface implemented by the *producer.* It allows the *consumer* to manage the lifecycle of portlets exposed in the service description. These exposed portlets can be cloned and customized at the *consumer* portal. Note that the original portlets exposed in the service description cannot be modified.

Important points to note is that WSRP based web services are synchronous and UI-oriented. *Consumers* can invoke the web service in the usual way and interact with the service UI. The typical browser-server interaction protocol is then translated into protocol suitable for *consumers* of user facing web services. A typical processing would consist of the following steps:

- The web service interfaces exposed by the *producer* to the *consumer* are described using Web Services Description Language (WSDL). WSDL is the mandatory interface between the client and service that enables the client to bind to the service and use it;
- Optionally, *consumers* can be registered in a *producer's* portal;
- Portal detects the remote portlet on its page and sends getMarkup() message to the *producer.* The markup interface supports end user interaction and it is another mandatory interface in WSRP;
- In response it receives a HTML fragment from the *producer;*
- Portal (*consumer*) aggregates the fragment into the portal page; and
- Optional functionality is the use of the portlet management. The portlet management defines operations (API) for cloning, customizing and deleting portlets.

The actual interaction between WSRP *consumers* and *producers* is more complex. We assume that the user can dynamically add a portlet to the portal page. In response, the portal invokes the WSRP remote service. This action specifies a new portlet instance that allocates a corresponding portlet instance on the portal side. When a user wants to view this portlet, the portal obtains the WSRP markup that defines the fragment to be displayed. The returned markup contains portlet action links and/or a portlet session identifier. When the user clicks on the link (*Click-on-Action*), a request goes from the browser to the portal. The portal maps the request into the invocation of the WSRP service. The capability to maintain the session identity is provided through the parameters that are passed, such as the session ID. This allows the WSRP service to look up the previous session details. When the user does not want to access the WSRP service any more, the session is closed, the portlet is removed, and its instance is destroyed.

WSRP PROCESSING SCENARIOS

The goal of WSRP is to make implementation of remote web services and access to the remote content easy. WSRP service scenarios come in several flavours ranging from simple view to complex interactions and configurations. Please note that our examples are based on IBM's WebSphere 5.1 Portal server. Some of the operations could be implemented differently on IBM Websphere 6.1 Portal or on other vendors' platforms. There are typically three different situations to deal with remote portlets: simple case of just processing view portlet, user interaction and dealing with the state information, and handling of configuration and customization.

REGISTRATION PROCESS

We have to start with two steps which have to be performed in all scenarios at the *consumer* portal:

Registering with the producer portal allows the *producer* to be known to the consumer and make available the list of WSRP services that could be consumed by the consumer portal. There are possible situations:

- Consumer has *online* access to the *producer.* In this scenario it is possible to use the XML configuration interface to configure new *producer* and remote web services. If in-band registration is supported in the producer, the consumer can register through the WSRP registration port type (register() call).

   a. If in-band registration is not supported by the producer, the consumer administrator must manually obtain the registration handle from the *producer*'s administrator.
   b. If the registration is required by the *producer*, it is necessary to implement a registration validation process for informing the producer whether a registration data from the consumer are valid.
- If the *consumer* works *offline* with regard to the *producer,* only the XML configuration interface can be used to create a *producer.*

Consuming the WSRP service allows you to integrate WSRP services from registered *producers* into the *consumer* portal and interact with them as they were local portlets.

WSRP 2.0 provides additional APIs relevant to the portlet lifetime: `set|RegistrationLifetime` and `getRegistrationLifetime` which allow the management of the registration.

SIMPLE VIEW PORTLET

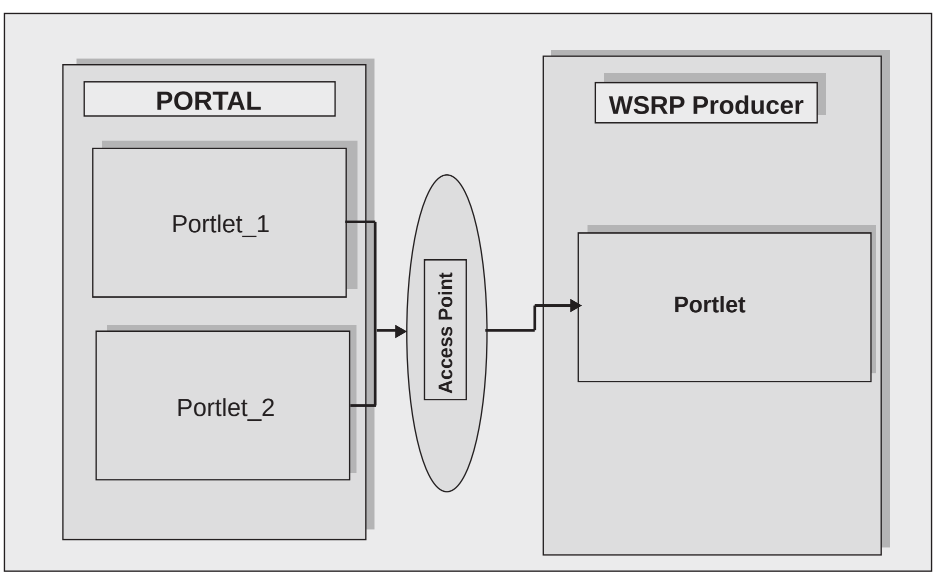
In our simple View portlet example, we assume that the web service requires only to be viewed by the end-user. Portlet has to be rendered and no interaction or forms are implemented.

Based on our description of available APIs, we need only `getMarkup()`operation to be implemented (Figure 2). This operation returns WSRP markup fragment which is then aggregated in the portal page.

INTERACTIVE SERVICE WITH TRANSIENT CONVERSATIONAL STATE

In this scenario, we need the WSRP implementation to support user interaction and maintain the conversational state of the application. Similarly to servlets (Servlets Specification 2.4 (2004)), the WSRP protocol operates over stateless HTTP. In order to generate correct responses, the application must be stateful and maintain its state. The state

Figure 2. Simple view portlet



may span across several request/response cycles. The WSRP protocol distinguishes between two states: transient and persistent (Figure 3). `Navigational state` is used when *producer* requires generation of markup for the portlet, several times during its conversation with the *consumer*. This state locally encapsulates required data needed to keep track of the conversation about the current state of the portlet. It means that the *producer* does not hold the transient state locally and the user can store or bookmark the URL using the navigational state. The state is stored with the URL only and both *page refresh* and *bookmarked pages* generate the output the end user expects. The session state is maintained using `sessionID` which is generated when the portlet initializes the session for a particular end-user. During the interaction the `sessionID` is moved between the *producer* and *consumer*.

The persistent state survives the conversation and will cease to exist only when either *consumer* or *producer* are discarded. The persistent state is the property exposed by the *producer* via the portlet management interface. In the case of registration (`Consumer Registration`), the registration state is maintained with the help of the `registrationHandle` generated during the consumer registration. WSRP protocol allows the consumer to customize the portlet and keep its state using `portletHandle`.

As an example we use again the University course offerings service that provides an overview of subjects offered in different semesters and allows users to click on the course offerings to navigate to the individual subjects and then on a "back-link" navigate back to the course offerings. Such a service should maintain conversational state within a *WSRP Session* to always display the correct view for a particular user and return a session ID for an internally managed session in each response of the `getMarkup()` operation (Figure 4). The markup returned may also contain links that will trigger invocations of the `performBlockingInteraction()` operation. This operation allows the portlet to perform logical operations updating state that could be shared with other portlets at the *producer*.

INTERACTIVE SERVICE CONTAINING PERSISTENT DATA

Let us consider a remote service that maintains configuration data that can be associated with

Figure 3. WSRP states

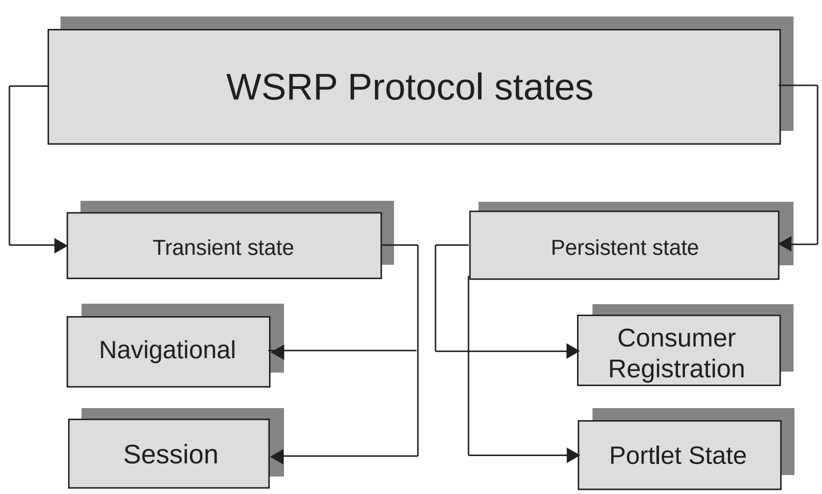


Figure 4. Conversational interactive services

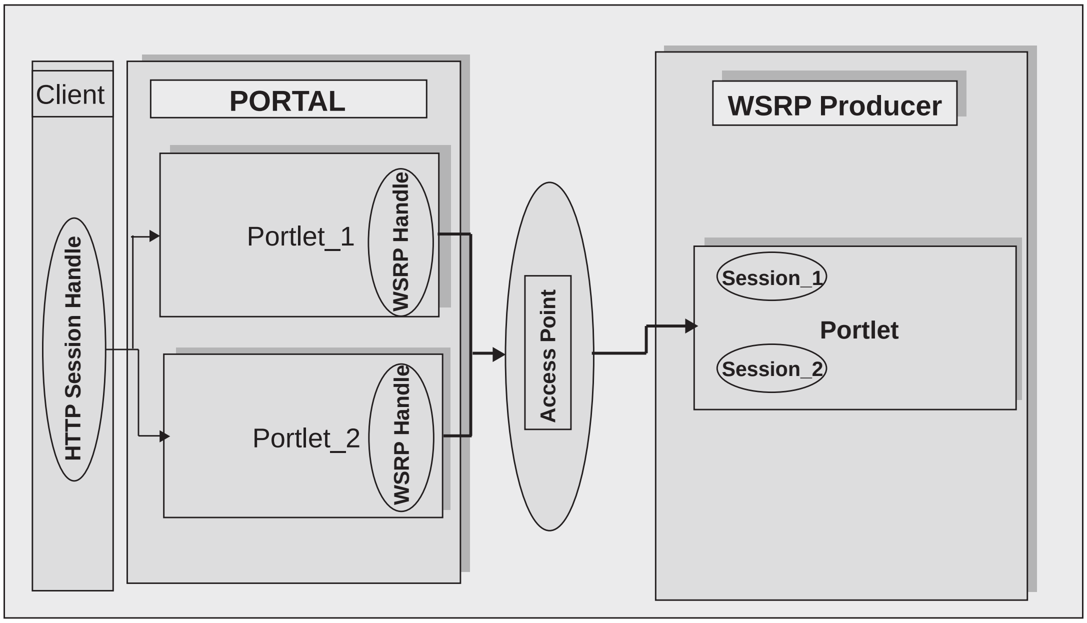


individual portlets available from the *producer*. An example for such a service is a tutorial allocation service that allows individual users to define their own personal schedules for tutorials. This situation requires the implementation of configuration data and ability to retain application persistent state for the end user.

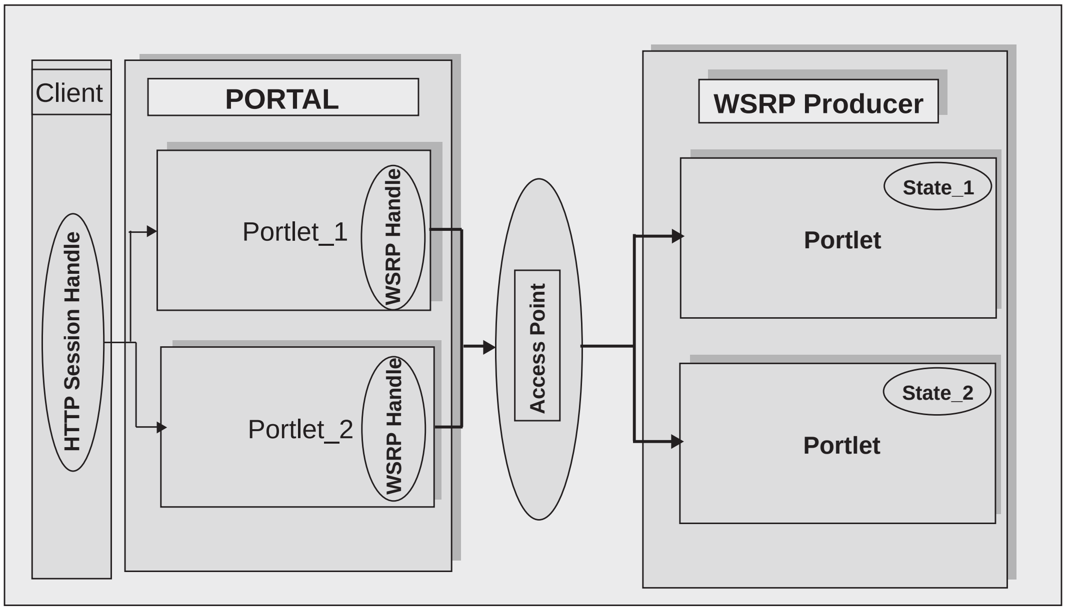
Since customization of portlets is not available in WSRP protocol, the *consumers* create new portlets using `clonePortlet` (Figure 5), specifying an existing portlet – either a producer offered portlet or one previously cloned by the consumer. The new portlet will be initialized with the same configuration data as the existing portlet. New portlets can also be cloned during the processing of a `performBlockingInteraction()` method. This is enabled when the *consumer* sets a flag preventing the user to customize the configuration data of the supplied portlet. The clone operation returns a portlet with updated configuration data and the customization is allowed. The portlet implementation can also make an attempt to update its configuration. This attempt typically results in the *producer* cloning the configuration data and applying the update to the cloned configuration. In either of these cases, the consumer obtains a handle (`portletHandle`) for referring to the new portlet when calling the *producer*.

When a portlet is no longer needed, it can be discarded by calling `destroyPortlets()`, passing the portlet handle. At this point, all persistent data can be discarded as well.

INTERACTIVE SERVICE CONTAINING CONFIGURATION DATA AND MAINTAINING SESSION

The *producer* may need to use both configuration data and transient session state to satisfy the application requirements. Several remote sessions may be associated with a portlet at any given time. For example, many remote sessions to the same portlet may exist for a *consumer* that is a portal with shared pages referencing the portlet and being used concurrently by multiple end users (Figure 6).

Figure 5. Interactive service with configuration data



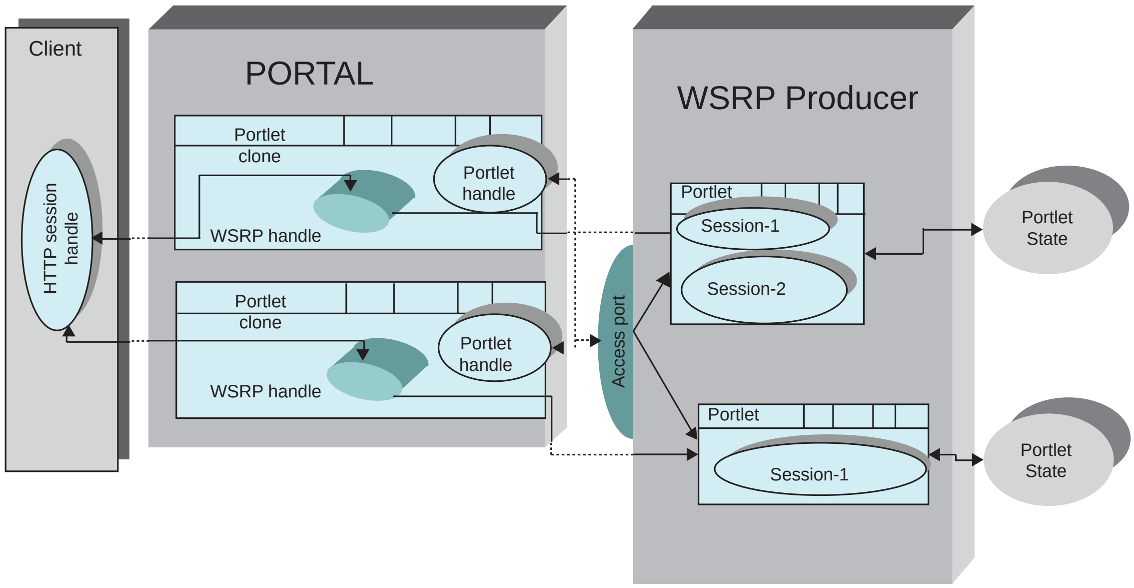
A typical information flow pattern starts with the end-user adding the remote portlet to a page. This is done for example by portal administrators via administration interface or XML configuration interface. The portlet invokes `clonePortlet()` operation on the remote service specifying an existing portlet and optionally including pre-configuration data. In return it obtains a new portlet handle (`portletHandle`) that it stores together with a newly created portlet instance on the portal database. The reason for cloning is that the original portlets exposed in the service description cannot be customized.

In the view mode, the portal determines the portlet handle (`portletHandle`) and uses it to make a call to the `getMarkup()` operation of the remote service. The operation returns the HTML fragment to be aggregated and displayed in the page within a `doView()` operation.. The response may contain action links, and could include a session handle (`sessionID`) if the portlet wants to maintain the conversation state. The portal typically needs to rewrite any action links to point to the *consumer* site and must store any returned session handle in a manner that allows it to be used on subsequent requests.

When the user clicks on an action link in the markup, a HTTP request is sent from the browser to the portal. The portal processes the request and maps it to an invocation of the `performBlockingInteraction()` operation of the remote service and passes the `sessionID` which allows the remote service to look up the associated session state. In the `performBlockingInteraction()` invocation, the remote service typically changes the state. When the `performBlockingInteraction()` operation returns, the portal refreshes the page. This results in an invocation of `getMarkup()` on all the portlets on the page and starts a new user-interaction cycle.

When an end user is finished with a portlet instance and discards it from a portal page, the portal recovers the handle of the portlet which is no longer needed and invokes `destroyPortlets()` on the remote service. The remote service discards the portlet and is free to release any resources associated with this portlet.

Figure 6. Interactive service with configuration data and session maintenance



RESTFUL WEB SERVICES

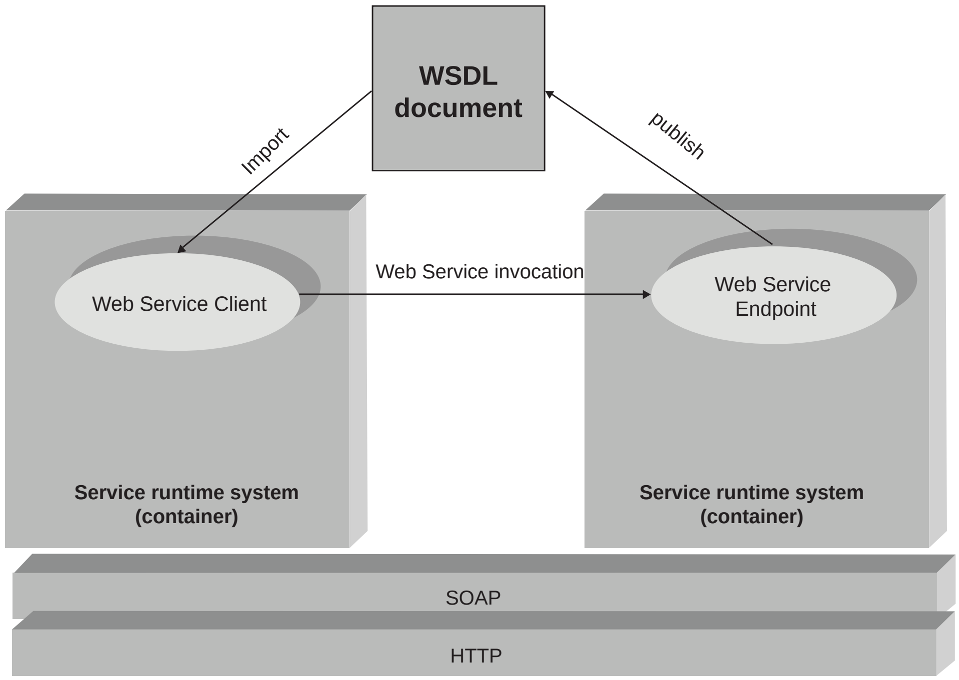
Data oriented web services are characterised by their complexity. Their development involves implementing various infrastructural components (WSDL, SOAP). Web services solution has to invest in creating a robust Web service infrastructure model. From the development point of view, it becomes increasingly complex to design and learn the technology. Presentation oriented services such as WSRP based services provide relief from the complexity of the infrastructure. The newly introduced features from JSR 286 provide sufficient flexibility in terms of inter-portlet communication and event processing, AJAX use, and resource serving capability. The presentation logic embedded in the remote portlet takes care of the easy rendering.

The new wave in web services are the RESTful Web services characterised by a simple XML-over-HTTP transmission. The RESTful services encapsulate data in a simple XML form and transport it over HTTP the same way as a Web page request. It takes full advantage of the REST architecture style which is related to a Web resource. In turn, this Web resource is a representation identified by a Uniform Resource Indicator (URI). The resource can be any persistent entity, and queries or updates the resource are applied through the URI and therefore influence a state change in its representation. In REST, a user to invoke operations on a Web resource using HTTP request methods in a Web service style. REST is closely associated with HTTP and leverages all HTTP features, such as methods, headers, and types.

ROLE OF UDDI IN WEB SERVICES

Portlets (JSR 168 (2005)) provide user interface to data delivered from web services. Before we explain the remote portlet publishing and discovery process in UDDI, we need to refresh the concept of publishing and discovering the web services in UDDI (Hugo Haas, P. L. H., Jean-Jacques Moreau, David Orchard, Jeffrey Schlimmer, Sanjiva Weerawarana (2004)). Web services expose their interfaces by registering in

Figure 7. Publish-Find-Bind Mechanism in UDDI



UDDI (UDDI Specifications (2005)). The web service consumer must find the service, bind to it and invoke the service. The basic mechanism for publishing and discovering data – oriented Web services is in Figure 7.

Regardless of whether the web service will be accessible to a single enterprise or to other companies (public access), the details about the service (its interface, parameters, location, etc.) must be made available to *consumers*. This is accomplished with a WSDL description of the Web service and a Web service directory where the details of the Web service are published (refer to Web Services Description Language (WSDL)). There are three steps which have to be performed in order to discover and use a web service published in the UDDI:

Publishing web service (step 1): In order to be accessible to interested parties, the web service is published in a Registry or web service directory. There are several choices regarding where to publish a web service:

1. If the web service is intended for the general public then a well-known registry is recommended. Consequently the WSDL description together with any XML schemas referenced by this description is made public.
2. The web service intended for enterprise use over an intranet should be published in a corporate registry only. No public access from the outside of the firewall is required.
3. Finally, providing all clients are dedicated partners in business, and there is an existing agreement on usage of this service, the web service can be published on a well-known location on the company server - with proper security access protection. Such a server would be placed on the public side of the company firewall but it would allow limited access, similar to a B2B Web server.
4. Web services directories are made up of a repository and the taxonomies (classification of registered entities for easier search) as-

sociated with them. There are no restrictions on publishing the web service in multiple registries, or in multiple categories.

Discovery of web service (step 2): Registry implementations can differ but there are some common steps, outlined below, that the client must perform before it can discover and bind (step 3) to the service:

1. The client must determine how to access the web service's methods, such as determining the service method parameters, return values, and so forth. This is referred to as *discovering the service definition interface*.
2. The client must locate the actual web service (find its address). This is referred to as *discovering the service implementation*.

Bind to the web service and invoke it (step 3): The client must be able to bind to the service's specific location. The following types of binding may occur:

1. Static binding during client development or at the deployment time.
2. Dynamic binding (at runtime).

From the client point of view, the binding type and time play important roles in possible scenarios relevant to the client's usage of the web service. The following situations are typical:

1. A web service (WSDL and XML schemas) is published in well-known locations. The developers of the application that use the service know the service, its location, and the interface. The client (which is a process running on a host) can bypass the registry and use the service interfaces directly. Alternatively, the client knows the location and can statically bind to the service at the deployment time.
2. The web service expects its clients to be able to easily find the interface at build time. These clients are often generic clients. Such clients can dynamically find the specific implementation at runtime using the registry. Dynamic runtime binding is required.

Development of web service clients requires some rules to be applied and design decisions to be made regarding which binding type is more appropriate for the given situation (static or dynamic binding). Three possible cases are discussed:

1. *Discovering the service interface definition*: If we are dealing with a known service interface, and the service implementation is known (no registry is required), the actual binding should be static.
2. *Discovering the service implementation*: In this case, static binding is also appropriate because we know the interface. We need to discover the service implementation only at build time.
3. The client does not know the service interface and needs to discover the service interface dynamically at build time. The service implementation is *discovered dynamically at runtime*. This type of invocation is called Dynamic Invocation Interface (DII). In this case, the binding must be dynamic.

Each WSDL description of the service published in UDDI must contain the following six elements: definitions, types, message, portType, binding, and service. The main elements of the UDDI data model are listed below (Figure 8):

- `businessEntity` represents the physical company which registered the services with UDDI;
- `businessService` represents a specific service offered by a company;
- `bindingTemplate` contains instructions for service invocation;

- publisherAssertion structure allows businesses to publish relationships between businessEntities within the company; and
- `tModel` is a structure similar to a database table. It contains the following information about an entity: the name, description, URL, and the unique key.

The relationships between the description and actual registered structures are outlined in Figure 9. The `portType` is represented by a UDDI structure called `tModel`. This `tModel` is categorized using unified *Category System* and the WSDL `EntityType` structure. The relevant *Category System* is known as WSDL `portType tModel` category and distinguishes it from other types of `tModels` with which the service might be associated.

A WSDL binding is also represented by a `tModel` structure. This is the binding `tModel` structure. This kind of categorization uses the same *Category System* as the `portType` tModel, but with a different key value to differentiate a binding tModel from a portType tModel.

The WSDL may represent a web service interface for an existing service. However, there may be an existing UDDI `businessService` that is suitable, and WSDL information can be just added to that existing service. If there is no suitable existing service found in the UDDI registry, a new `businessService` must be created. Finally, the WSDL binding port is represented by UDDI `bindingTemplate`. A WSDL service may contain multiple ports. These ports are exactly mirrored by the containment relationship in a UDDI `businessService` and its `bindingTemplates`.

REGISTERING WSRP SERVICES AS REMOTE PORTLETS IN UDDI

WSRP *producer* is considered as a web service on its own, exposing multiple `Bindings` and `Port-`

Figure 8. UDDI model composition

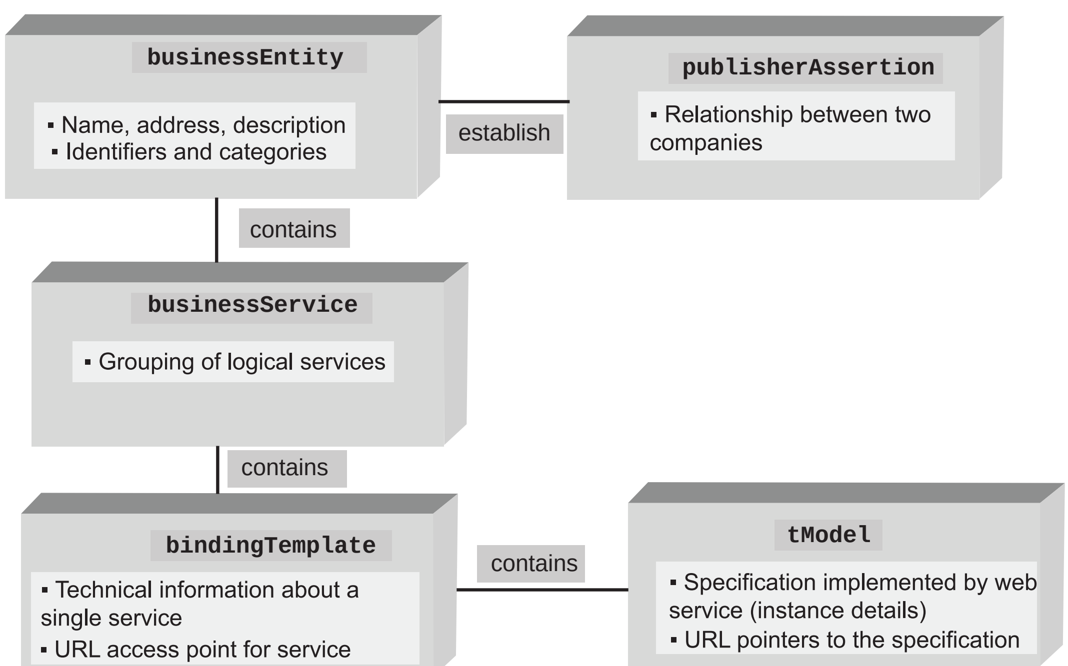


Figure 9. Mapping from WSDL to UDDI

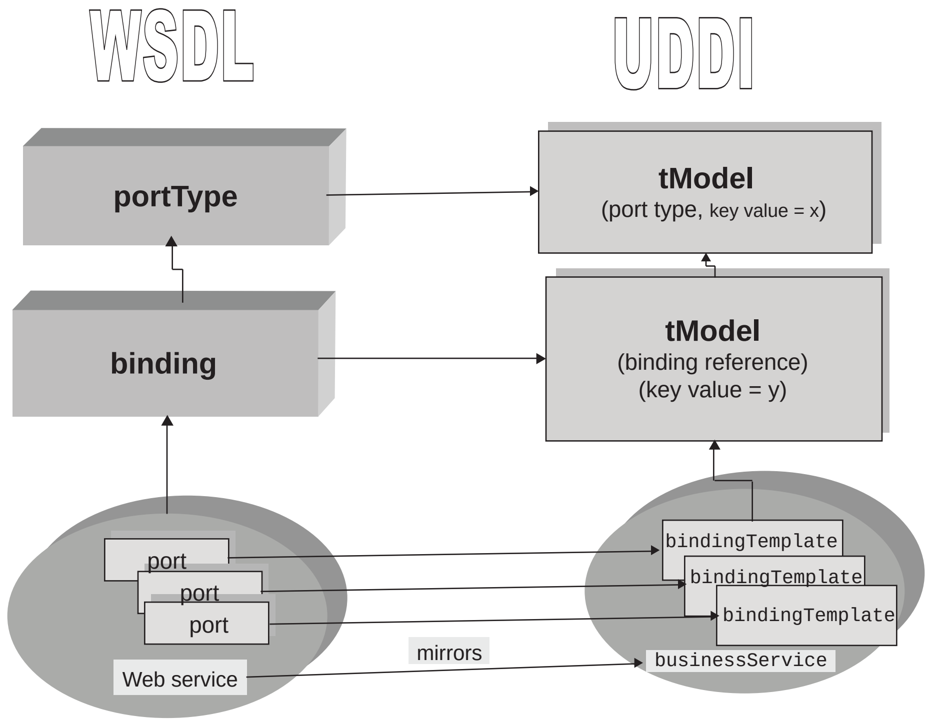


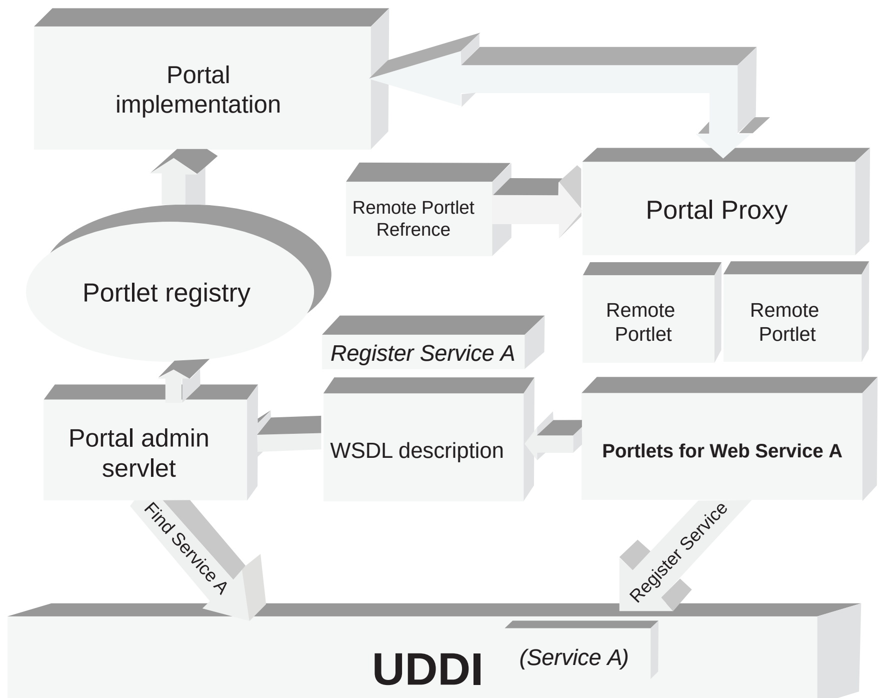
`Types`. It is described through the WSRP WSDL services description and some additional portlet types. Portlets are not fully fledged services, they are only HTML fragments. Therefore, they do not expose `PortType, binding` template and access points. The portlet is exposed by its *producer* and *consumer* interacts indirectly with remote portlets using the *producer's* infrastructure. The remote portlet is addressed by a `portletHandle` defined within the *producer's* scope.

Figure 10 shows an example how a portal finds and integrates a remote portlet published in the UDDI. Content or application providers (known as WSRP *producers*) implement their service as WSRP service and publish it in a globally accessible directory. *Producer's* WSDL description provides the necessary information about remote service actual end-points. The directory lets the *consumers* easily find the required service. Directory entries, published in WSDL format, briefly describe the WSRP components and offer access to details about the services. The portal administrator uses the portal's published functions to create remote portlet web service entries in the portal local registry. Furthermore, the portlet proxy binds to the WSRP component through SOAP, and the remote portlet invocation (RPI) protocol ensures the proper interaction between both parties.

Typical discovery and binding steps are summarized below:

- A provider offers a set of portlets and makes them available by setting up a WSRP *producer* and exposing them as remote portlets. These portlets are then made available to other businesses by publishing them in a UDDI registry. The provider may perform

Figure 10. Publishing and locating remote portlets with the UDDI



the publishing task either through a custom built user interface or through the interface provided by a UDDI Server.

- End-user wants to add a portlet to his own portal. Using the tools provided by his portal (for example portal administrative interface or a custom-written XML interface[1]), he/she searches for remote portlets. After finding the suitable remote portlet, these portlets can be added to the portal pages. Alternatively, a portal administrator could search the UDDI registry for portlets and make them available to end-users by adding them to the portal's internal database.
- The user can now access the page containing newly added and running remote portlets. Behind the scenes, the portal is making a web service call to the remote *producer*, and the *producer* is returning a markup fragment with the required data for the portal to render on the portal page.

In order to provide necessary information about remote portlets, WSRP extended the definition of the bind namespace for `portTypes` and SOAP binding. The following extensions are defined (WSRP specification version 1 (2003). This WSDL defines the following `portTypes` (normative definitions):

- **WSRP_v1_Markup_PortType:** This is the port on which the Markup Interface can be accessed. All *producers* must expose this `portType`.
- **WSRP_v1_ServiceDescription_PortType:** This is the port on which the Service Description Interface can be accessed. All *producers* must expose this `portType`.
- **WSRP_v1_Registration_PortType:** This is the port on which the Registration Interface can be accessed. Only *producers* supporting in-band registration of *consumers* need expose this `portType`.

- **WSRP_v1_PortletManagement_PortType:** This is the port on which the Management Interface can be accessed. *Producers* supporting the portlet management interface expose this `portType`. If this `portType` is not exposed, the portlets of the service cannot be configured by consumers.

SOAP bindings for these `portTypes` are listed below:

1. **WSRP_v1_Markup_Binding_SOAP:** All *producers* must expose a port with this binding for the `WSRP_v1_Markup_PortType` (the `Markup portType`).
2. **WSRP_v1_ServiceDescription_Binding_SOAP:** All *producers* must expose a port with this binding for the `WSRP_v1_ServiceDescription_PortType` (`ServiceDescription portType`).
3. **WSRP_v1_Registration_Binding_SOAP:** *Producers* supporting the `Registration portType` must expose a port with this binding for the `WSRP_v1_Registration_PortType`.
4. **WSRP_v1_PortletManagement_Binding_SOAP:** *Producers* supporting the `PortletManagement portType` must expose a port with this binding for the `WSRP_v1_PortletManagement_PortType`.

Web service is typically represented by several remote portlets and relevant WSDL description (Figure 11) which contains pointers to all required and optional WSRP portlet interfaces (e.g. registration interface, service description, etc.) in the form of a `portType`.

In essence, WSRP *producers* are web services. They expose `PortTypes` and `bindings` which the *consumers* can use to access and interact with. It means that the process of publishing a *producer* corresponds to publishing a web services together with associated portlet metadata. Besides the `portletHandle`, the `Portlet Title` and textual description, all further portlet metadata are missing in the UDDI. These remaining metadata must be retrieved from the respective ports (`ServiceDescription portType` or `PortletManagement portType`).

Presentation oriented service has been developed to ease the burden of complexity of data oriented services. Specifically, to eliminate the need of developing the presentation logic at the consumer site. It is still using SOAP as main transport feature. There is still need to take into account the binding to service markup and service description.

SUMMARY AND CRITICAL LOOK AT WSRP

WSRP can be used to create powerful portal services from originally non-portal-centric applications. WSRP provides easy access to remote web services and their user-facing representations. Web services offer a mechanism to create remotely accessible and platform independent services. Portlet standard - JSR 168 - complements this mechanism by defining a common platform and APIs for developing user interfaces in the form of portlets. WSRP enables reuse of these portlets. Only one generic proxy is required to establish the connection. The WSRP could be used to facilitate the development of an entire network of presentation-oriented web services. It would allow the portal users easily discover and use any number of remote services. There is no need to develop custom adapters, build client interfaces, and spend time locally deploying the customized portlets.

WSRP 1.0 is lacking any standard for transaction handling, there are some problems associated with security, reliability, and load balancing[2]. Furthermore, the response time could be unpredictably long. The portal pages are aggregated from multiple *producers* and portal must wait until all

fragments are ready for rendering. Any remote service may slow down the entire portal.

WSRP 2.0 is fully aligned with the portlet specification 286 and contains all additional features announced with JSR 286. Therefore, it supports building composite applications using coordination means. The event and public parameters support loose coupled event paradigm. Similar as JSR 286 it also allows for additional AJAX use cases utilizing resource serving through the portlet. The capability of setting HTTP headers and cookies, filters, request dispatching provides a framework for better integration with servlets.

Using WSRP and UDDI extension for remote portlets, makes the end-user completely shielded from the technical details of WSRP. In contrast to the standard use of data-oriented web services, any changes to web service structure are implemented within the remote portlet and the *consumer* is not affected by these changes.

UDDI version 1.1 allows the *producers* to describe its presence together with each of the services it offers. The most important feature planned for higher versions of UDDI specification (specifically version 2 and higher) is the provision of cross portlet communication. Portlets should be able to broadcast their event information to other portlets spread across multiple *producers* if necessary. This feature allows other portlets to tailor their generated content according to broadcasted events. This feature is being well supported by the WSRP 2 which enables the inter portlet communication on the consumer site.

So far, there is seemingly no need to publish remaining portlet metadata. However, we envisage that the concept of semantic web and web service matchmaking as outlined in R. Akkiraju, R. Goodwin, Prashant Doshi, Sascha Roeder (2003) will require better annotation of available remote portlets functionalities to be published in a public registry. In such case, searching for portlets defining certain metadata values in UDDI will become the necessity.

Comparing WSRP and RESTful Web service, the latter does not provide any presentation logic. However, RESTfull web services rely on standard HTTP protocol, utilizing the power of the resource URI to maintain the resource state. WSRP uses classic web service infrastructure (WSDL, UDDI and SOAP), which still requires the negotiation of various contracts between the provider and consumer. The burden of the implementation is leveraged by the presentation logic being provided by the producer.

With data oriented services, the portlet displaying web service's raw data arriving from `a UDDI businessService` structure (web service) reflects the infrastructure of the web service and needs to bind to the service.This is an undesirably tight coupling of user interface and service raw data which often cause problems to the *consumer* in time of any changes to web service raw data. This problem is typically resolved by the *producer* providing relevant libraries.

Chapter 7.11
Hyperlink Structure Inspired by Web Usage

Pawan Lingras
Saint Mary's University, Canada

Rucha Lingras
Saint Mary's University, Canada

ABSTRACT

This chapter describes how Web usage patterns can be used to improve the navigational structure of a Web site. The discussion begins with an illustration of visualization tools that study aggregate and individual link traversals. The use of data mining techniques such as classification, association, and sequence analysis to discover knowledge about Web usage, such as navigational patterns, is also discussed. Finally, a graph theoretic algorithm to create an optimal navigational hyperlink structure, based on known navigation patterns, is presented. The discussion is supported by analysis of real-world datasets.

DOI: 10.4018/978-1-59904-990-8.ch024

INTRODUCTION

The structure of a Web site is usually based on how the designer envisions the site will be used. However once the Web site is put into use, the designer's theoretical approach may turn out to be not so practical. It is only the actual use of the Web site that will give the designer clues about how the users navigate through the site and in what content they are most interested. For example, if the users are flocking towards a particular type of content, then the designer could think about establishing the site as an authority on that type of content by providing more information on the topic. Conversely, if a type of content is not generating much attention, it may be because the users are missing the information. The designer may look into changing its location on the Web site.

The users' navigational patterns help reveal the users' interests, but they can also be used to adjust the hyperlink structure of the Web site for optimal navigation. This chapter describes how Web usage can be used to construct a hyperlink structure that is easier to navigate. The discussion includes data visualization, uncovering navigational patterns using conventional data mining techniques, as well as a graph theoretical algorithm to construct an improved navigational structure.

The second section of this paper provides a background on various tools to analyze Web navigation. The next section describes an application of data mining techniques to discover Web navigation patterns. An algorithm to create an optimal hyperlink structure is presented in afterwards. The chapter concludes by summarizing the content and identifying areas for future research and development.

BACKGROUND

Web usage mining applies data mining techniques to discover usage patterns from Web data, in order to understand and better serve the needs of Web-based applications. While Web content mining and Web structure mining utilize the information found in Web documents, Web usage mining uses secondary data generated by the users' interaction with the Web. Web access logs available on most servers are good examples of the datasets used in Web usage mining. Other Web usage data may include browser logs, user profiles, registration files, user sessions or transactions, user queries, bookmark folders, as well as mouse clicks and scrolls (Kosala and Blockeel, 2000). Web usage mining includes the creation of user profiles, as well as analysing user access patterns and navigation paths.

Prior to applying data mining techniques, it is essential to understand the dataset. This is typically done by creating multiple summary reports and, if possible, using visual representations. Before writing programs for analyzing Web access logs, one may want to consider one of the analysis tools already available. These analysis tools may provide answers to most questions regarding the usage of Web sites. The list below provides the freeware and open source Web access analysis tools listed on an Open Directory Web site (http://dmoz.org/). In addition to freeware and open source tools, the listing of commercial tools can also be found on the Open Directory site. This section provides a discussion on how to obtain summary reports, visualization of aggregate clickstream, as well as individual user sessions from Web access logs.

One of the more popular analysis tools is called Analog (www.Analog.cx). Analog analyses Web access log files and produces summary reports that can be used to enhance the content of the Web site. The information provided by Analog includes the frequently accessed pages on a Web site and the search terms used to find these pages. Analog also provides temporal analysis that can be used to ensure sufficient bandwidth for the users. The summary reports provided by Analog, however, are of limited use for link analysis. In this section, we will review two software packages, Pathalizer and StatViz, which allow us to visualize the aggregate link usage and track individual user sessions.

We will illustrate the usage of these analysis tools using data obtained from the Web access logs of an introductory first year course in Computing Science at Saint Mary's University over a sixteen-week period. The initial number of students in the course was 180. Over the course of the semester, this number was reduced to 130-140 students. Certain areas of the Web site were protected, meaning users could only access them using their IDs and passwords. The users' activities in the restricted parts of the Web site consisted of submitting profiles, changing passwords, submitting assignments, viewing the submissions, accessing the discussion board, and viewing current class marks. The public portion of the Web site consisted of viewing the course information, lab manual, class-notes, class assignments, and lab assignments. If the users only accessed the public Web site, their IDs would be unknown. To protect user privacy, the usernames for the rest of the entries were changed to "user". The dataset and its analysis using Analog can be found in Akerkar and Lingras (2007). In this chapter, we will discuss visual representations of the students' link usage and navigation paths.

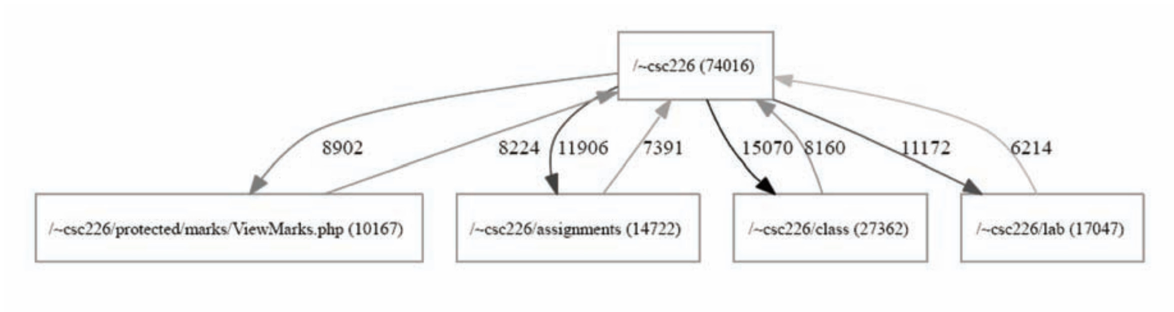
Analysis of Clickstreams: Visually Studying Navigation Paths

Pathalizer (2006) is a visualization tool that shows the most frequent paths taken by users when browsing a Web site. This information can be useful for improving the navigation within a Web site. In conjunction with the summarization of Web logs, the visual representation of navigation can also be used to determine which parts of the site need most attention.

Figure 1 shows a graph drawn by Pathalizer for the top eight traversed links in our sample Web log. Every node in Figure 1 is a page. The path/URL for the page and the number of hits on the page are listed within the boxes (or nodes). Every arrow represents a user visiting those two pages in succession. The width and the number associated with the arrow represent the number of times that path was taken (i.e., the thicker the arrow, the bigger the frequency).

Figure 1 tells us that one or more visitors directly went to all five pages shown. The homepage for the course was the most frequently visited page, and the link from the homepage to the class directory was the most frequently taken.

Figure 1. Top eight traversed links on the course Web site



The link from the homepage to the assignment page was the second most popular path, followed by the link from the homepage to the lab folder. This knowledge of popular pages and links provides a suggested hyperlink structure by telling us that:

- Every page should have a link to the homepage, and
- Links to the class folder, assignment, and lab folder should be prominently displayed on the homepage.

The specification of eight links to Pathalizer only gave us a bird eye view of the Web site. If we wish to have a more detailed analysis, we would need to increase the number of edges in the filter section of the application. However, there are problems with adding more edges in the analysis. As the number of edges increases, it is difficult to read the graph because of the large amount of information, as well as the smaller text size. More details about aggregate link usage can be found in Akerkar and Lingras (2007).

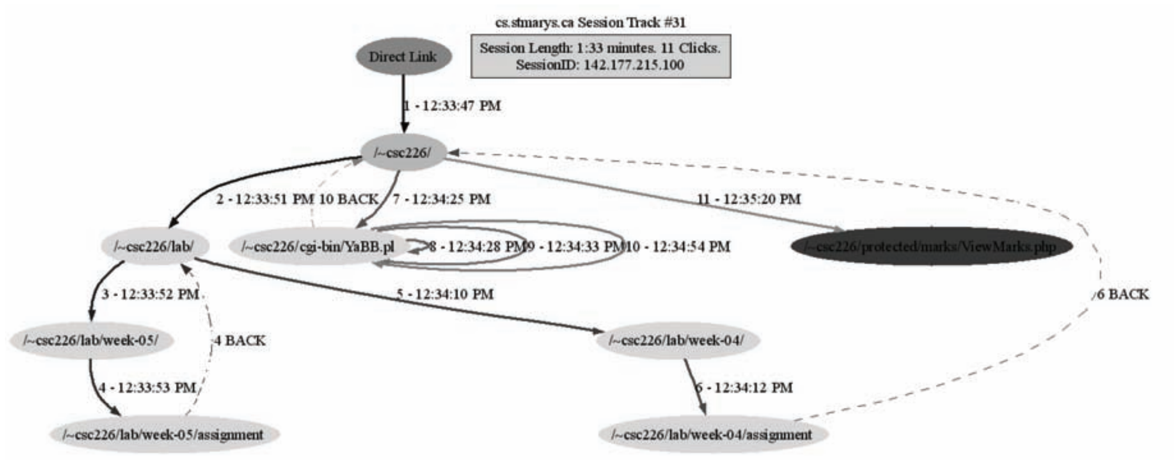
Visualizing Individual User Sessions

In the previous section, we looked at aggregate Web usage analysis. In this section, we will look at individual user interaction with a Web site. Since a Web site generally has a large number of visitors, it is practically impossible to analyze each one in great detail. However, one can randomly pick sessions of various sizes to study how individual visitors traverse through a Web site. Such an analysis should always be a precursor to the actual Web usage or data mining. Sometimes, such a visualization process may also be conducted after uncovering interesting navigational patterns from the data mining exercise. For example, if an e-Commerce Web site experiences a category of users aborting their sale, the site manager may pick a session from a list of such pre-emptive users and study the visual representation of their navigation pattern.

StatViz (2006) can be used to track the movements within an individual session stored in a logfile, from page to page. A session is simply associated with an IP address, which means all requests from a given computer are considered to be for the same session. This is not a good assumption, especially for a public computer. The session track reporter will produce one graph per session. Each graph is designed to give a good sampling of how visitors move around the site.

Tracking individual sessions is a computationally intensive activity. Moreover, it is difficult to study all the user sessions individually. Therefore, we selected a 1.25 hour snapshot from our classlog.txt. The time period that was chosen was from 11:30 am to 12:45 pm on a Tuesday (October 9, 2001). Usually, this time reports fairly intensive activity on the course Web site, as it follows the class and there are two labs

Figure 2. Tracking an individual Web session using StatViz



scheduled in parallel during that time. We picked three sessions of different lengths (Akerkar and Lingras, 2007). Due to space limitations, we will only show one session in this chapter, which is represented in Figure 2.

A graphical display of individual session tracks will allow us to understand how the students successfully or unsuccessfully navigate through the Web site. Studying these graphs will not only help us understand the information needs of our visitors, but also provide insight into how we could better present information on the Web site to facilitate easier navigation. Let us try to interpret the StatViz graph from Figure 2.

- The graph shows movement through the Web site as links from one page to another.
- Each node is a Web page; each solid line is a "click" from one page to the other as indicated by the arrow.
- Each line has a number next to it representing the number of that particular "click" in the session track, i.e. the sequence order. The time of the "click" is also shown next to the number.
- In some cases, there is also a dashed line with the same number as another click. These "BACK" links indicate that the visitor went back to that page using the back button before proceeding.
- Pages that are not on our site (external referrers) are shown as brown ovals.
- While Figure 2 is depicted in black and white in this chapter, the software colours the "entry" page green and the "exit" page red. If the entry and exit pages are the same, that page will be red.

Figure 2 shows an off-campus session which is relatively brief, lasting a little over 1.5 minutes. The IP number starting with 142.177 tells us that the user comes from an Internet service provided by the local phone company. Again, the user seemed to know what he or she was looking for. The user either used a bookmark or typed the URL directly to get to the entry page (green colored) /~csc226/. The user then proceeded with three clicks to look at the assignment for week-05, came back to the lab folder with the back button, and used two clicks to look at the assignment from previous week (week-04). The user then used the back button to get to the course homepage. Clicks 7-10 were used to browse the bulletin board. Finally, the user checked their marks and then exited the site. The user also knew the structure of the site very well.

This is why he or she managed to conduct three separate activities in a relatively short period of time: view two lab assignments, browse bulletin board, and view marks. This student's individual session track shows a successful navigation and suggests that the data on the Web site is displayed effectively. In order to come to this conclusion though, more individual sessions would have to be analysed.

In this section, we discussed data visualization techniques that can be used to understand the hyperlink usage from a Web log. Once we have some understanding of the overall navigation patterns on a Web site, we can use data mining techniques to look for interesting patterns.

DATA MINING TO DISCOVER NAVIGATION PATTERNS

The data in Web access logs are intrinsically sequential. We used data visualization techniques to look at aggregate navigation using Pathalizer, as well as navigation in individual sessions using StatViz. Applying data mining techniques to analyze sequences of Web requests is an important area of research (Cadez, *et al.*, 2000; Iváncsy and Vajk, 2006). Many of the techniques involved are at an experimental stage and contain sophisticated mathematical analysis.

Classification and Association Modeling of Web Navigation

Classification is one of the data mining techniques that can contribute to Web usage mining. Web personalization (Dai and Mobasher, 2003) is a common application of classification integrated in Web usage mining. The interest in Web personalization can be traced back to the Firefly system (obsolete URL: www.firefly.com), which was used to suggest music CDs that match the user's interests. The user's interests were determined by analyzing their navigation through the site. Similar attempts can also be seen on Amazon.com. When a user requests information about a book, the system provides a list of additional books. The list consists of books purchased by people who bought the same book that interests the user. Attempts at Web personalization are increasing at a rapid rate. The greater interest is also leading to more formal frameworks for Web personalization (Perkowitz and Etzioni, 1997). Joachim, *et al.* (1995) propose the use of a tour guide approach. Perkowitz and Etzioni (1997) attempt to formalize the concept of adaptive Web sites. Adaptive Web sites are defined as those that automatically improve their organization and presentation by learning from visitor access patterns. Perkowitz and Etzioni suggest that much of the earlier work has been focused on fairly simple adaptations such as automatically creating shortcuts on the Web site, and customizing the site to suit the needs of each individual user. They propose the use of sophisticated adaptations of Web sites to the users' needs, and aggregation of information gleaned from the user population to improve the navigation for a large number of users.

Baglioni, *et al.* (2003) used the classification algorithm C4.5 to develop a model to predict whether a user might be interested in visiting a section of a Web site based on the sections the user has already visited. The knowledge of the sections of interest will make it possible to create a personalized view of the Web site by using an on-the-fly menu or page reorganization.

There is a subtle difference between the classification model used by Baglioni, *et al.* (2003) and association mining. If one were to apply association mining, we would find pairs of channels that are accessed during the same session. The model developed by Baglioni, *et al.*, on the other hand, takes a list of channels of user interest and predicts the likelihood of the user accessing a given channel. The association mining conducted by Batista and Silva (2002) addressed essentially the same question as the one answered by the classification exercise reported in Baglioni, *et* *al.*, i.e. which category of articles are requested by the same visitor. Batista and Silva's approach falls into the classical *Market Basket Analysis* problem (Berry and Linoff, 1997).

The aim of market basket analysis is to find groups of items that are frequently referred together. In this case involving an online news site, a transaction is the Web request and the item is the news section from which the article can be found. Groups of items that occur frequently together in the same visit are called frequent itemsets (Agrawal and Srikant, 1994). A typical association mining process needs guidance for restricting the search space, usually in terms of a support threshold. The algorithms then find the itemsets that satisfy this minimum support threshold. Batista and Silva defined weak associations as those below 5% of the total number of occurrences, and heavy associations as those above 10%. The association mining results for the online news site showed strong associations between pairs such as (Politics, Society), (Politics, International News), and (Society, Local News).

Sequence Pattern Analysis of Web Logs

Cadez, *et al.* (2000) presented msnbc.com (2000) anonymous Web data that can be downloaded from: http://kdd.ics.uci.edu/databases/msnbc/msnbc.html. The data comes from msnbc.com's Web access logs and msn.com's news portions for the twenty-four hour period of September, 28, 1999. There were a total of 989,818 user sessions. The data is anonymized, so we have no knowledge of the login details of the users. We are also limited to knowing the category of the Web page that was requested by the user, and not the name of the actual page. The reporting of categories of pages as opposed to the actual pages in fact simplifies our job. There are anywhere from 10 to 5,000 pages per category and it would be difficult to keep track of each one of these pages. As with any other Web access logs, any page request served via a caching mechanism could not be recorded in the data.

One of the most useful pieces of information in the Web access logs is the sequences in which pages are accessed by users. Each sequence in the dataset corresponds to a user's Web request. The average length of the sequences is 5.7. Sequences can be used to provide appropriate links to simplify the navigation. One can do a frequency analysis of all the category pairs, such as (1,1), (1,2), (1,3),…,(17,1), (17,2),…,(17,3). In total, there are $17 \times 17 = 289$ pairs. The sequence of category numbers in a pair is important for two reasons:

- The links are always between a pair of pages. Thus, knowing which pages are requested from a given page is the most relevant information needed in order to determine the navigational links.
- The pairs of sequences will have the highest frequency. For example, a sequence (i,j,k) cannot have a higher frequency than either of the pairs, (i,j) or (j,k).

Analysis of the paired sequences reveals interesting information. For example, 138,441 users first accessed a page from category 1 followed by another page in the same category, i.e. 1. Conversely, only two users first read an article from category 17 and then moved to a page from category 16. The pairs that stay within the same category – such as the top four sequences, (1,1), (2,2), (14,14), (8,8) – tend to have higher frequencies. This seems reasonable because once a user starts reading an article from one category he or she is likely to access another article from the same category. Usually, such sequences would be well served by the Web structure, since the Web site is likely to provide reasonable navigation between articles within the same category. The pairs where one of the categories is 1 (corresponding to front page) tends to have higher frequencies. (The fifth highest frequency is for the pair (1,2).)

This sequence probably corresponds to users first coming to the front page and then following links to other categories. These sequences will also be better served by the Web site, because the front page will have links to other categories.

The pair (6,7) with a frequency of 25,106 is the first pair with two distinct categories, neither of which is front page. Category 6 is “on-air” and category 7 is “misc”. The high frequency for this pair suggests that the Web site should provide easy navigation from “on-air” to “misc”. On the other end of the spectrum, analysis shows very little movement between some of the categories. There are three possible explanations for such a lack of migration:

- These categories have limited contents, and hence very few visitors. For example, only 2,032 users accessed a page from category 16 (bbs).
- These categories attract different types of readers.
- The link structure does not make it possible to easily navigate between these categories. The Web administrator may consider improving the navigational structure.

The aforementioned discussion shows how one can interpret paired sequences of Web usage to study the Web structure. One can extend such an analysis to longer sequences. There are a total of 17 × 17 × 17 = 4913 triplets. Similar to the paired sequences, the triplets where all three pages are from the same category tend to have higher frequencies. The triplets where the three categories are not distinct do not provide any additional knowledge about user behaviour than the one gathered from paired sequences. Therefore, we will focus only on triplets where all three categories are distinct. The first such pair is (1,7,4), which corresponds to frontpage-misc-local. This information could probably be used to put the links to categories 7 and 4 next to each other on pages from categories 1.

One could extend the analysis to longer sequences. However, it should be noted that 635 of the 4913 triplets had a frequency of 0. The longer sequences with distinct categories would have smaller and smaller frequencies, since the average length of sequences is only 5.7. Another possible analysis could include compressing the sequences by replacing multiple sequential articles from the same categories, and then analyzing the resulting sequences. For example, a sequence “3 2 2 4 2 2 2 3 3” could be represented as “3 2 4 2 3” that shows how a user migrates from one category to next.

The msnbc.com data (2000) has been subject to more sophisticated analysis by a number of researchers. Cadez, *et al.* (2000) partition users from msnbc.com into clusters based on similarity in their navigation paths through the site. The clustering approach is model-based (as opposed to sequence of length based approaches we have seen thus far). It partitions users according to the order in which they request Web pages. Cadez, *et al.* use a mixture of first-order Markov models using the Expectation-Maximization algorithm. They display aggregate paths for each cluster. As expected from our earlier analysis, the larger clusters tend to have a navigation path that seems to navigate within a given category.

Iváncsy and Vajk (2006) show how the automata theory can be used for discovering frequent Web navigation patterns from the msnbc.com data. The SM-Tree algorithm discovers the frequent page sequences using finite state machines. The navigation patterns are rarely sequential. Sometimes users use the back button to go back one level and then traverse to the next page. Such navigation is best represented using a tree. Iváncsy and Vajk show how the PDTree algorithm based on pushdown automaton can be used to identify the tree-like Web navigation patterns.

The following section describes how Lingras and Lingras (2007) use the sequence analysis of Web page accesses to create weighted directed graphs. The information contained in such graphs can be used to improve the Web surfing experience.

CREATING AN OPTIMAL HYPERLINK STRUCTURE USING GRAPH THEORY

In this section, we will use the MSNBC data of Web access patterns (2000) to develop a graph theoretic model of Web usage sequences for optimal navigation within the Web site (Lingras and Lingras, 2007). An ideal navigational structure would limit the number of outgoing links from a page, provide an adequate number of incoming links to a page, and also ensure that most transfers between pages can happen within two to three clicks. Two important granular concepts, namely neighborhood systems (Krishnan and Raghavachari, 2001) and rough set theory (Lin, 2003) are used to propose concepts of primary, secondary, and tertiary neighborhood. These neighborhoods are used to formalize the aforementioned requirements of an ideal navigational structure. A modification of the minimal spanning tree algorithm is also shown to be useful for developing an optimal hyperlink structure.

Graph of Web Usage Sequences

A graph G is defined using a pair of set (V, E), where V is a set of vertices and E is a set of edges. For directed graphs, edges are ordered pairs, i.e. $E = \{(u, v) \mid u, v \in V\}$. For undirected graphs, the edges are sets of vertices with a cardinality of two, i.e. $E = \{\{u, v\} \mid u, v \in V\}$. Let us look at a more specific example of a Web graph. Let $V = \{home, cat_1, cat_2, cat_3, page_1, page_2, \bullet\bullet\bullet, page_9\}$ be the Web pages on a Web site. If we have links from every page to every other page in V, we can reach any page from any other page with a single click. However, such a fully connected graph will mean that every page must have twelve links. A large number of links on a page may overwhelm a user, especially on a site that has several thousand pages. The user would also be more likely to miss certain links, as a large number of links would lead to clutter. However, if a page has reasonably small number of links, the user is more likely to notice all of them. Reducing the number of links, though, will make it necessary for a user to follow multiple links in order to reach a desired page. These two competing goals can be defined using the concepts of primary, secondary, and tertiary neighborhoods as follows.

The primary neighborhood for a Web page p, $N_1(p)$, is defined as the set of Web pages that can be reached using a single click. Mathematically, we can write it as: $N_1(p) = \{v \in V \mid (p, v) \in E\}$. The secondary neighborhood, $N_2(p)$, for a Web page is defined as the set of Web pages that can be reached using two or fewer clicks. The tertiary neighborhood, $N_3(p)$, for a Web page is defined as the set of Web pages that can be reached using three or fewer clicks. It is possible to define neighborhood for higher degrees such as $N_4(p)$ or $N_5(p)$ as well.

The neighborhood concept used here is borrowed from the neighborhood systems proposed by Lin (2003). The primary neighborhood is similar to the lower bound in rough set theory (Pawlak, 1992). The higher degree neighborhoods can be viewed as a generalization of the upper bound.

It can be easily seen that secondary neighborhood of a page is a union of the primary neighborhood of the page with primary neighborhoods of all the pages in its primary neighborhood, such as:

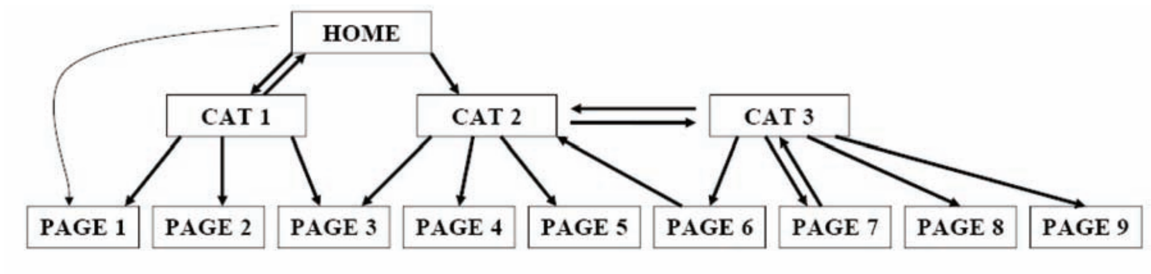
$$N_2(p) = N_1(p) \cup \bigcup_{v \in N_1(p)} N_1(v)$$

Similarly,

$$N_3(p) = N_2(p) \cup \bigcup_{v \in N_2(p)} N_1(v)$$

Our goal is to:

Figure 3. Example of an optimal navigation structure



i. Restrict the size of $N_1(p)$ to make sure that the page is not cluttered with too many hyperlinks.
ii. Ensure that for every Web page access (p, v),$v \in N_3(p)$. (We can use higher degree neighborhoods such as $N_4(p)$ or $N_5(p)$ if it is appropriate.)

Figure 3 shows a possibly optimal navigational structure for our example set of Web pages. As we can see, the cardinality of primary neighborhood is less than or equal to three. Moreover, each page has at least two incoming hyperlinks. The following are some of the primary and secondary neighborhoods:

$N_1(home) = \{cat_1, cat_2, page_1\}$

$N_1(cat_1) = \{page_1, page_2, page_3, home\}$

$N_1(cat_2) = \{page_3, page_4, page_5, cat_3\}$

$N_1(page_1) = \varnothing$.

$$\begin{aligned} N_2(home) &= N_1(home) \cup N_1(cat_1) \cup N_1(cat_2) \cup N_1(page_1) \\ &= \{cat_1,\ cat_2\ \ page_1\ \ page_2\ \ page_3\ home,\ cat_3,\ page_4,\ page_5\} \end{aligned}$$

Since we do not know the Web page access sequences, we cannot verify that the tertiary neighborhoods will include all the Web page access sequences.

In order to develop an algorithm that achieves the aforementioned goal, we will be using a weighted directed graph, where a weight is associated with each edge. Figure 1 shows an example of a weighted Web graph for a course offered at Saint Mary's University.

Usually, the weights represent a cost associated with the edge. Therefore, most graph theoretical algorithms are designed to minimize the sums of weights. Thus, we will have to take an inverse of the number of Web page accesses as our weights, as described below, for the MSNBC data. There will be an edge from every category to every other category. Since the weights represent a cost associated with that edge, we use the following formula:

$$w_{(u,v)} = \frac{\text{Average frequency of a paired sequence}}{frequency_{(u,v)}}$$

It is easily seen that the smaller the weight the more popular the edge.

We can use the concept of a spanning tree to find the smallest number of links for a Web site. A spanning tree for a connected undirected graph is defined as a subgraph with the same number of vertices as the original graph, with the minimum number of edges to keep all the vertices connected to each other. A minimum spanning tree is a spanning tree with smallest sum of edge weights.

We will modify the notion of the spanning tree for our Web graph based on the assumption that every well-designed Web site has a link to "Home" from all the pages. Therefore, we do not need to consider any edges to the root in our analysis. That means, as long as there is a path from the root to

Figure 4. Algorithm to find an optimal hyperlink structure

1) Definitions:
   - Let $G = (V, E)$ be the original Web graph and $G_t = (V_t, E_t)$ be its minimum spanning Web graph.
   - Let V_{temp} be a temporary set of vertices.
   - Let C be the set of candidate edges.
   - Let $unused$ be the set of unused edges.
   - Let $desiredInDegree$ be the desired number of incoming edges for each vertex.
   - Let $inDegree$ be the current number of incoming edges for each vertex.
2) Initialization:
   - $V_{temp} = \{root\}$.
   - $C = \{(root, x) | (root, x) \in E\}$.
   - $unused = \emptyset$.
   - $inDegree = 0$.
3) While New Vertex is added to V_{temp} and $V_{temp} \neq V$
   - Remove the edge (u, v) with smallest weight from C
   - If $v \notin V_{temp}$ Then
     - Add v to V_{temp}.
     - Add all the edges (v, y) from E to C.
     - Add (u, v) to E_t.
     - Add a penalty δ to all the edges (u, x) that are in C and $unused$.
   - Else
     - Add (u, v) to $unused$.
4) If $inDegree == 1$ Then $V_t = V_{temp}$
5) If $inDegree < desiredInDegree$ Then
   - Increment $inDegree$
   - $V_t = \{root\}$
   - Add all the edges from $unused$ to C.
   - $unused = \emptyset$.
   - go to Step 3.

every page, all the pages are connected to each other. Hence, we can define a spanning Web tree as a subgraph of a Web graph such that:

- There is a designated vertex called root that corresponds to the homepage or frontpage of the site, which has no incoming edges,
- all the vertices other than the root have exactly one incoming edge and the weights of the edges are the minimum.

Preliminary analysis of the Web page access sequences from MSNBC suggests that one will end up with the Web tree that is in the form of a star with most of the Web pages connected directly to the homepage. This means that there will be too many links on the homepage, which, as discussed before, would not be advantageous. To avoid too many links on a page, we can add a penalty to the weights of the remaining edges from a vertex, whenever an edge from the vertex is added to the spanning Web tree. The penalty helps in restricting the size of the primary neighborhood for each page. In order to increase the chances of including all the Web page access sequences in tertiary neighborhood, we deviate from the minimum spanning Web tree by allowing multiple incoming edges for each node. The resulting Web graphs will result in larger tertiary neighborhoods. The algorithm is shown in Figure 4.

If *desiredInDegree* = 1, the algorithm given in

Figure 5. Suggested hyperlink structure for MSNBC

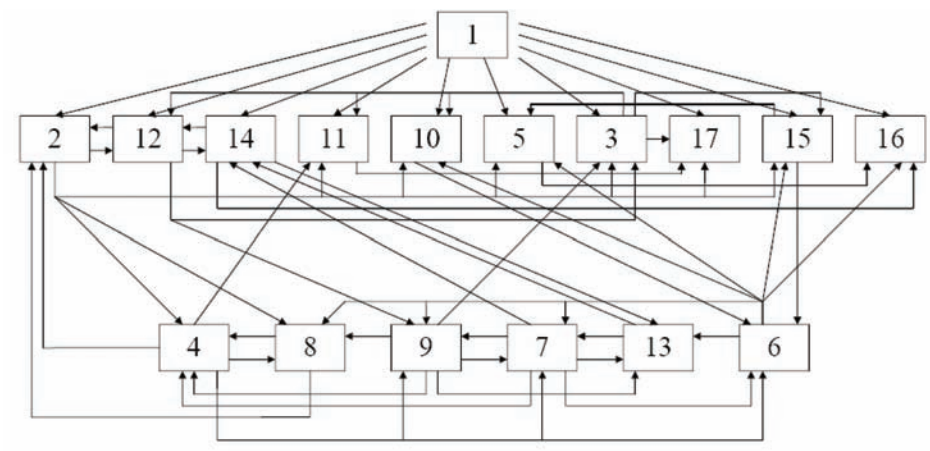


Figure 4 will result in a minimum spanning Web tree. While a minimum spanning Web tree provides navigation from each vertex to every other vertex by going through the root using the link to "Home", one may want to provide additional navigation paths to these nodes. We can add these additional paths to the hyperlink structure by specifying larger values for *desiredInDegree*. The algorithm will add more incoming links to each vertex, if they exist in the original graph.

Analysis of the Graph of Web Usage Sequences

We applied the algorithm shown in Figure 4 to the frequency of transitions between two categories from msnbc.com. We experimented with different values of *desiredInDegree* and *delta* (the penalty). We found that *desiredInDegree* = 4 and *delta* = 0.1 gave us a reasonable hyperlink structure, as shown in Figure 5.

The *desiredInDegree* of 4 did result in all vertices having four incoming edges. However, the algorithm does allow for less than four incoming edges if four incoming edges did not in fact exist.

In the secondary neighborhood (with the root or "Home" being the primary neighborhood), the amount of outgoing edges varies. For example, Category 2 has nine outgoing edges, while Category 11 only has one. One can conclude that even greater importance should be placed on Category 2.

The tertiary neighborhood (with the root or "Home" being the primary neighborhood) also contains an important vertex, Category 6, which has outgoing edges and points to eight vertices. The large amount of outgoing edges in Category 2 and Category 6 may be a reason why a greater penalty should be put into place. A greater penalty to the weights would decrease the amount of links and thus clutter on a page.

The graph contains many symmetric links, i.e. it contains many pairs having an incoming and outgoing edge to each other. Examples include: (7, 13) (13, 7); (2, 12) (12, 2); (12, 14) (14, 12); (9, 7) (7, 9); and (4, 8) (8, 4). Clearly, these categories belong to the same logical group.

It is interesting to note that while most vertices from the tertiary neighborhood have at least one incoming edge from the secondary neighborhood, Category 7 only has incoming edges from other tertiary neighborhood members. This shows that Category 7 may generate a highly specific target audience. But, it also runs the risk of easily being "lost" among all the other categories.

CONCLUSION AND FUTURE RESEARCH AND DEVELOPMENT

In this chapter, we explored various ways to analyse and improve a Web site's hyperlink structure. Web access logs were used to study user navigation patterns, which can be used to create a hyperlink structure that provides better navigation. We looked at various tools, such as Pathalizer and StatViz, to visualize the Web navigation. We also discovered the various ways data mining techniques could be applied, including gathering more knowledge about Web usage and creating a more personalized Web experience. Finally, we discussed how the minimum spanning tree algorithm can be extended to create a Web graph that provides a possibly optimal navigational structure based on Web usage patterns. An ideal navigational structure would provide easier navigation by limiting the number of outgoing links from a page while still providing an adequate number of incoming links, which would ensure most transfers between pages happening within two or three clicks.

Creating dynamic Web pages based on predicted user needs is one of today's most popular areas of research. These attempts are usually referred to as the adaptive Web; it assumes that one can quickly understand what the user wants and quickly create an appropriate navigation page. In some cases, it is possible to categorize a Web user with their initial navigational patterns. However, this first judgement does not always reflect the user's developed navigation as they become more comfortable with the Web site or if their interests change. This chapter describes a restructuring of the current static Web structure on a regular basis. Such a restructured Web site will cater to majority of Web visitors, without having to make a quick judgement about their navigations intentions. There is currently limited research in this area. The authors believe that more Web site designers will start bringing the knowledge of Web usage in determining Web structure. The algorithm presented in this chapter is an initial step in this direction. A theoretical framework such as the one described in (Lingras, 2007) will play a key role in further development.

Chapter 7.12
Search Engine-Based Web Information Extraction

Gijs Geleijnse
Philips Research, The Netherlands

Jan Korst
Philips Research, The Netherlands

ABSTRACT

In this chapter we discuss approaches to find, extract, and structure information from natural language texts on the Web. Such structured information can be expressed and shared using the standard Semantic Web languages and hence be machine interpreted. In this chapter we focus on two tasks in Web information extraction. The first part focuses on mining facts from the Web, while in the second part, we present an approach to collect community-based meta-data. A search engine is used to retrieve potentially relevant texts. From these texts, instances and relations are extracted. The proposed approaches are illustrated using various case-studies, showing that we can reliably extract information from the Web using simple techniques.

INTRODUCTION

Suppose we are interested in *'the countries where Burger King can be found'*, *'the Dutch cities with a university of technology'* or perhaps *'the genre of the music of Miles Davis'*. For such diverse factual information needs, the World Wide Web in general and a search engine in particular can provide a solution. Experienced users of search engines are able to construct queries that are likely to access documents containing the desired information. However, current search engines retrieve Web pages, not the information itself[1]. We have to search within the search results in order to acquire the information. Moreover, we make implicit use of our knowledge (e.g. of the language and the domain), to interpret the Web pages.

DOI: 10.4018/978-1-60566-112-4.ch009

Table 1. Comparison between the Web as a corpus and 'traditional' corpora

Web Corpus	Newspaper Corpus
Redundancy. Because of the size of the Web, we can expect information to be duplicated, or formulated in various ways. If we are interested in a fact, we have to be able to identify just one of the formulations to extract it.	**No or fewer redundancy.** Especially for smaller corpora, we cannot expect that information is redundantly present.
Temporal and unreliable. The content of the Web is created over several years by numerous contributors. The data is thus unreliable and may be out-dated.	**Constant and reliable**. In corpus-based IE, it is assumed that the information in the corpus is correct and up-to-date.
Multilingual and heterogeneous. The Web is not restricted to a single language and the texts are produced by numerous authors for diverse audiences.	**Often monolingual and homogeneous.** If the author or nature (e.g. articles from the Wall Street Journal) of the corpus is known beforehand, it is easier to develop heuristics or to train named entity recognizers.
No representative annotated corpora. As no representative annotated texts are available, the Web as a corpus is currently less suited for supervised machine learning approaches.	**Annotated test corpora available.** In order to train supervised learning based named entity recognizers (NERs), test corpora are available where instances of a limited number of classes are marked within the text.
Dynamic. The contents of the Web changes continuously, results of experiments may thus also change over time.	**Static.** Experimental results are independent of time and place as the corpora are static.
Facts and opinions. As a multitude of users contribute to the Web, its contents are also suited for opinion mining.	**Facts only.** Information Extraction tasks on Newspaper corpora mainly focus on the identification of facts.

Apart from factual information, the Web is the de-facto source to gather community-based data as people with numerous backgrounds, interests and ideas contribute to the content of the Web. Hence the Web is a valuable source to extract opinions, characterizations and perceived relatedness between items.

In this chapter, the focus is on gathering and structuring information from the 'traditional' Web. This structured information can be represented (and shared) using the standard Semantic Web (SW) languages. Hence, this chapter focuses on the automatic creation of content for the SW. For simplicity, we abstract from the SW standards RDF(S)/OWL.

The Web-as-a-Corpus vs. Traditional Text Corpora

Information extraction (IE) is the task of identifying instances (or *named entities*) and relations between those instances in a collection of texts, called a text corpus.

In the nineties, the Message Understanding Conferences (MUC) focused on the recognition of named entities (such as names of persons and organizations) in a collection of texts (Chinchor, 1998). Initially, this work was mostly based on rules on the syntax and context of such named entities. For example, two capitalized words preceded by *mr.* will denote the name of a male person. As the creation of such rules is a laborious task, approaches became popular where named entities were recognized using machine learning (Mitchell, 1997), for example in (Zhou & Su, 2002; Brothwick, 1999; Finkel, Grenager, & Manning, 2005). However, such approaches typically make use of annotated training sets where instances (e.g. '*Microsoft'*) are labeled with their class *('Organization'*).

Traditional information extraction tasks focus on the identification of named entities in large text corpora such as collections newspaper articles or biomedical texts. In this chapter however, we focus on the Web as a corpus. In Table 1 the most important differences between the two can be found.

Suppose that we are interested in a list of all countries in the world with their capitals. When we extract information from a collection of newspaper articles (e.g. 3 months of the New York Times), we cannot expect all information to be present. At best, we can try to discover every country-capital combination that is expressed within the corpus. When we use the Web however, all the required information can be expected to be present. Moreover each of the combinations is likely to be expressed on various pages with multiple formulations. For example, *'Amsterdam is the capital of the Netherlands'* and *'The Netherlands and its capital Amsterdam (...)'* are different formulations of the same fact. In principle, we have to be able to interpret only one of the formulations to extract the country-capital combination. Hence, in comparison with a 'traditional' newspaper corpus, we can both set different objectives and apply different methods to extract information from the Web.

Heterogeneous vs. Homogeneous Sources

In this work we focus on unstructured natural language texts. Information extraction from structured sources is thoroughly described in for example (Chang, Kayed, Girgis, & Shaalan, 2006) and (Crescenzi & Mecca, 2004).These 'wrappers' make use of the homogeneous lay-out of large Web sites. Large Web sites such as *amazon.com* and *imdb.com* make use of a database and present automatically generated Web pages. The lay-out is uniform over the whole site, but the information changes from page to page. The performing artist, the title of the album and other catalogue data can be found on the exact same place on the page. The HTML-source of the two pages will also only differ at these places. For pages within a large Web site, a wrapper algorithm can be created the information of interest from an arbitrary page within the site. Wrappers are relatively simple and time efficient. However, they are Web site and thus domain dependent. Instead we focus on information from arbitrary Web sites in this chapter.

Fact Mining

The first part of this chapter discusses a method to extract factual information from the Web. To formalize the concept *information* we define an initial ontology on the domain of interest (e.g. movies, literature, hamburger restaurants). Given this initial ontology, we populate it with extracted knowledge. For example, if we consider an ontology with the classes *Movie* and *Actor*, we can populate the ontology by finding instances of these classes. Hence, if we identify the terms *'Top Gun'*, *'The Godfather'* as movie titles and the terms *'Tom Cruise'* and *'Marlon Brando'* as actors we can add these terms as instances to the ontology. Moreover if acts-in is a relation between Movie and Actor, then the challenge is to discover the instances of that relation from texts on the Web, e.g. (*Marlon Brando, The Godfather*).

In Section 2 of this chapter, we present an algorithm that—given a domain of interest—extracts, structures and combines information from the Web. With structured information available, we can easily find the information we are interested in. The extracted information can, e.g. be used by recommender systems to acquire additional metadata. This metadata can be used to make meaningful recommendations for music or TV programs. For example, suppose a user has expressed a preference for TV programs relating to Italy. The recommender system will be able to recognize regions as *Tuscany* and *Veneto* and cities as *Milano* and *Florence* using extracted information. Occurrences of such terms in a program guide description will mark a program as relevant. Likewise, if the user has expressed a preference for TV programs relating to photography the system will be able to recognize the names of famous photographers as *Cartier-Bresson* and *Moholy-Nagy*.

Community-Based Knowledge Mining

The Web is not only a well-suited text corpus to mine factual information. As a large community of users contributes to the contents of the Web, it can also be used to mine more subjective knowledge. For example, we call Paul Gauguin a post-impressionist and to be similar to Vincent van Gogh, *Christina Aguilera* a pop artist similar to *Britney Spears*. Such qualifications may not all be facts, but are thoughts shared by a large community.

In the second part of the chapter we focus on methods to automatically find such internet community-based meta-data. On the one hand we classify instances (e.g. pop artists) into categories and on the other hand identifying a distance matrix of related instances. The information found can be used to create an automated folksonomy: a knowledge base where items are tagged using implicit input from multiple users.

In restricted domains (e.g. Movies) in fact mining, the use of wrappers may be well usable. The Internet Movie Database[2] for example is a reliable, semi-structured source to extract data on movies. When we are interested in subjective data based on opinions of the Web community however, we cannot restrict ourselves to a single source. We combine data from multiple Web sites, and thus multiple contributors, to characterize instances. We can however use semi-structured data from social Websites such as *last.fm* as a benchmark on restricted domains like music (Geleijnse, Schedl, & Knees, 2007).

Related Work

Information extraction and ontology constructing are two closely related fields. For reliable information extraction, we need background information, e.g. an ontology. On the other hand, we need information extraction to generate broad and highly usable ontologies. An good overview on state-of-the-art ontology learning from text can be found in (Buitelaar, Cimiano, & Magnini, 2005).

Early work on relation identification from the Web can be found in (Brin, 1998). Brin describes a Web site-dependent system to identify hypertext patterns that express a given relation. For each Web site, such patterns are learned and explored to identify instances that are similarly related. SnowBall (Agichtein & Gravano, 2000) is a successor of Brin's system with an embedded named-entity recognizer. The idea of extracting relations using patterns is similar to one of the methods presented here. However, in Snowball the relations gathered are not evaluated.

KnowItAll is a hybrid named-entity extraction system (Etzioni et al., 2005) that finds lists of instances of a given class from the Web using a search engine. It combines hyponym patterns (Hearst, 1992) and learned patterns for instances of the class to identify and extract named-entities. Moreover, it uses adaptive wrapper algorithms (Crescenzi & Mecca, 2004) to extract information from html markup such as tables. Contrary to our method, it does not use instances to formulate queries. In (Downey, Etzioni, & Soderland, 2005) the information extracted by KnowItAll is evaluated using a combinatorial model based on the redundancy of information on the Web.

Cimiano and Staab (2004) describe a method to use a search engine to verify a hypothesis relation. For example, if we are interested in the 'is a' or hyponym relation and we have the instance Nile, we can use a search engine to query phrases expressing this relation (e.g. ''rivers such as the Nile'' and ''cities such as the Nile''). The number of hits to such queries is used to determine the validity of the hypothesis. Per instance, the number of queries is linear in the number of classes (e.g. city and river) considered.

In (de Boer, van Someren, & Wielinga, 2007) a number of documents on art styles are collected. Names of painters are identified within these documents. The documents are evaluated by counting the number of painters in a training set (of e.g. expressionists) that appear in the document. Painters appearing on the best ranked documents are then mapped to the style. De Boer et al. use a training set and page evaluation, where we simply observe co-occurrences.

A document based technique in artist clustering is described in (Knees, Pampalk, & Widmer, 2004). For all music artists in a given set, a number of documents is collected using a search engine. For sets of related artists a number of discriminative terms is learned. These terms are used to cluster the artists using support vector machines. The documents are obtained in a similar way in our document-based method. However, we restrict ourselves to identifying names of artists and categories in the documents.

The number of search engine *hits* for pairs of instances can be used to compute a semantic distance between the instances (Cilibrasi & Vitanyi, 2007). The nature of the relation is not identified, but the technique can for example be used to cluster related instances. In (Zadel & Fujinaga, 2004) a similar method is used to cluster artists using search engine counts. In (Schedl, Knees, & Widmer, 2005), the number of search engine hits of combinations of artists is used in clustering artists. However, the total number of hits provided by the search engine is an estimate and not always reliable (Véronis, 2006). In (Geleijnse, Korst, & de Boer, 2006) an approach is presented where one instance is queried and the resulting texts are mined for occurrences of other instances. Such an approach is not only more efficient in the number of queries, but also gives better results.

In (Pang, Lee, & Vaithyanathan, 2002; Dave & Lawrence, 2003; Kim & Hovy, 2004; Pang & Lee, 2005) methods are discussed to identify opinions on reviewed products. For example, given is a set of reviews of some flat screen television mined from the Web. The task is to assign a grade to the product or its specific features (e.g. the quality of the speakers).

The extraction of social networks using Web data is a frequently addressed topic. For example, Mori et al. (2006) use tf·idf (see (Manning & Schütze, 1999)) to identify relations between politicians and locations and (Jin, Matsuo, & Ishizuka, 2006) use inner-sentence co-occurrences of company names to identify a network of related companies.

FACT MINING

In this first part of the chapter, we will describe a method to populate an ontology, given a domain of interest. Here we only consider factual information, i.e. opinions and the like are here not taken into account but will be considered in the second part of this chapter.

Problem Definition

The Semantic Web community (Berners-Lee, Hendler, & Lassila, 2001) is providing standards for machine readable and interpretable information on the Web. The languages RDF(S) and OWL are developed for this purpose by the World Wide Web Consortium[3]. Dedicated reasoners are created for the semantic Web languages for ontology-based question-answering services. As such, these reasoners are able to provide answers to information demands like the above, given a sufficiently populated ontology.

For our purposes we define an ontology as follows:

Definitions. A reference ontology O is a 4-tuple (C, I, P,T), with:

C= $(c_0, c_1, \ldots, c_{N-1})$, an ordered set of N classes,
I = $(I_0, I_1, \ldots, I_{N-1})$, with I_j, $0 \le j < N$, the set of instances of class $c_j \in C$,
P = $(p_0, p_1, \ldots, p_{M-1})$, a set of M binary relations on the classes, with p_i: $c_{i,0} \times c_{i,1}$ $0 \le i < M$, and $c_{i,0}, c_{i,1} \in C$, and
T = $(T_0, T_1, \ldots, T_{M-1})$, is a set of instances of the

relations in P with $T_i = \{(s,o) \mid p_i(s,o)\}$ for each i, $0 \le i < M$

An *initial ontology* of O is defined as O' = (C, I', P,T'), where:

$I'_j \subseteq I_j$ for all j, $0 \le j < N$,
$T'_i \subseteq T_i$ for all i, $0 \le i < M$, and
$(s,o) \in T'_k \Rightarrow s \in I'_{k,0}\ o \in I'_{k,1}$ for some k

Popular search engines currently only give access to a limited list of possibly interesting Web pages. A user can get an idea of relevance of the pages presented by analyzing the title and the snippet presented. When a user has sent an accurate query to the search engine, the actual information required by the user can already be contained in the snippet.

We are interested whether the data in the snippets presented by a search engine is sufficient to extract information. With the definitions presented above, we formulate the information extraction problem as an ontology population problem:

Problem. Given an initial ontology O', extend O' to some O'' that maximizes the precision and/or recall.

We define precision and recall as measures of a class $c_j \in C$:

$$precision(c_j) = \frac{|I_j \cap I''_j|}{|I''_j|}$$

and

$$recall(c_j) = \frac{|I_j \cap I''_j|}{|I''_j|}$$

Similar measures can be formulated for relations p_i.

Global Outline

We choose to extract information from arbitrary Web sites. To find relevant Web sites—and thus relevant information—we use a state of the art search engine. Currently, both Google and Yahoo! allow a limited amount of automatic queries per day.

When using a search engine, we have to deal with the following restrictions.

1. The search engines return a limited number of search results per query (at most 5,000 per day using the *Yahoo! API*) .
2. We want to perform as few queries to a search engine as possible to limit the use of its services.

We therefore need accurate queries, for which we can expect the search engine to return relevant snippets. We therefore choose to use known instances in our queries to simultaneously find instances of classes and instances of relations. For example, given the instance '*Johan Cruijff'* in the initial ontology, we can use this instance in the query 'Johan Cruijff was born in' in order to retrieve a place in general and Cruijff's place of birth in particular. The place of birth, Amsterdam, can be extracted from the retrieved documents. Now, *'Amsterdam'* can be used in the query 'was born in Amsterdam' to discover other (Amsterdam-born) persons, like Willem Frederik Hermans and Paul Verhoeven.

For a given relation p_k, we thus use both an instance $I'_{k,0}$ and a natural language formulation of the relation in our queries. Subsequently, the snippets are scanned for instances of $I'_{k,1}$ and $(I'_{k,0}, I'_{k,1}) \in T'_k$. In Section 2.3 we focus on the identification of relation patterns. Section 2.4 handles the identification of instances of a class from the snippets. We combine these strategies into the ontology population algorithm as described in Section 2.5.

Identifying Effective Relation Patterns

Given is a relation p_k and a set T'_k of instances of p_k. For relation p_k, defined on $c_{k,0} \times c_{k,1}$, in the partial ontology O', we have to identify natural language formulations of this relation. We are thus interested in patterns P_k of the form "[$c_{k,0}$] expression [$c_{k,1}$]"[4] that express the relation p_k in natural language.

Say, for example, we consider the classes *'author'* and *'book title'* and the relation *'has written'*. We assume that we know some related instance-pairs, e.g. *('Leo Tolstoy', 'War and Peace'*) and *('Günter Grass', 'Die Blechtrommel'*). We then want to find natural language phrases that relate authors to the titles of the books they wrote. If we find phrases that typically connect two related terms (i.e. patterns), we can expect them to also connect other related instance-pairs. Thus, if we query a pattern in combination with the name of an author (e.g. *'Umberto Eco wrote'*), we want the search results of this query to contain the books by this author.

Such patterns have to meet two criteria:

- **Precision:** Preferably, the phrase is unambiguous, i.e. the probability that the terms found do not belong to the intended class must be small. For example, consider the relation place of *birth(Person, City)*. The pattern *[Person] was born in [City]* is an ambiguous representation of this relation, since *[Person] was born in* can precede a date or the name of a country as well.
- **Recall:** The pattern must frequently occur on the Web. Rare patterns are not likely to give much search results when querying such a pattern in combination with an instance.

Identifying Relation Patterns

We focus on the relation p_k in our ontology O. For easy reference, we assume $p_k = c_q \times c_a$. The problem is to identify a set of patterns that lead to highly relevant search results when queried in combination with instances of c_q. We first generate a list of relation patterns with the use of the following algorithm. For evaluation purposes, we also compute the frequency of each pattern found.

- **Step 1:** Formulate queries using an instance-pair $(x,y) \in T'_k$. Since we are interested in phrases within sentences rather than in keywords or expressions in telegram style that often appear in titles of Web pages, we use the allintext: option. This gives us only search results with the queried expression in the bodies of the documents rather than in the titles. We query both allintext:" x * y " and allintext:" y * x ". The * is a regular expression operator accepted by both Google and Yahoo!. It is a placeholder for zero or more words.
- **Step 2:** Send the queries to the search engine and collect the snippets of the pages it returns for each query.
- **Step 3:** Extract all phrases matching the queried expressions and replace both x and y by the names of their classes.
- **Step 4:** Remove all phrases that are not within one sentence.
- **Step 5:** Normalize all phrases by removing all mark-up that is ignored by the search engine. Since the search engines are case-insensitive and ignore punctuation, double spaces and the like, we translate all phrases found to a normal form: the simplest expression that we can query that leads to the document retrieved.
- **Step 6:** Update the frequencies of all normalized phrases found.

- **Step 7:** Repeat the procedure for any unqueried pair $(x', y') \in T'_k$

We now have generated a list with relation patterns and their frequencies within the retrieved snippets.

Selecting Relation Patterns

From the list of relation patterns found, we are interested in the most effective ones. We are not only interested in the most precise ones. For example, the retrieved pattern ''född 30 mars 1853 i'' proved to be a 100% precise pattern expressing the relation between a person ('Vincent van Gogh') and his place of birth ('Zundert'). Clearly, this rare phrase is unsuited to mine instance-pairs of this relation in general. On the other hand, high frequency of some pattern is no guarantee for effectiveness either. The frequently occurring pattern ''was born in London'' (found when querying for Thomas Bayes * England) is well-suited to be used to find London-born persons, but in general the pattern is unsuited—since too narrow—to express the relation between a person and his or her country of origin. Taking these observations into account, we formulate three criteria for selecting effective relation patterns.

1. The patterns should *frequently* occur on the Web, to increase the probability of getting any results when querying the pattern in combination with an instance.
2. The pattern should be *precise*. When we query a pattern in combination with an instance in I_q, we want to have many search results containing instances from c_a.
3. If relation R is not functional, the pattern should be *broad*, i.e. among the search results when querying a combination of the pattern and an instance in I_q there must be as many distinct R-related instances from c_a as possible.

To measure these criteria, we use the following scoring functions for a relation pattern s.

1. **Frequency**. (shown in Box 1)
2. **Precision**.

$$f_{prec} = \sum_{x \in I'q}^{n} \frac{P(s,x)}{|I'_q|}$$

For instances $x \in I'_q$, $I'_q \subseteq I_q$ we calculate P(s,x) as follows.

Where $F_I(s,x)$ and $F_O(s,x)$ are given as such in Box 2.

Box 1.

$f_{freq}(s)$ = "number of occurrences of s in the snippets as found by the algorithm described in the previous subsection"

Box 2.

$F_I(s, x)$ = "the number of snippets after querying s in combination with x containing instances of c_a" $F_0(s, x)$ = "the number of snippets found (at most 1,000)"

Box 3.

$B(s, x)$ = "the number of distinct instances of class c_a found after querying s in combination with x"

3. **Breadth**.

$$f_{spr} = \sum_{x \in I'q} B\left(s, x\right)$$

Where B(s,x) is defined in Box 3.

$B\left(s,x\right) =$ "the number of distinct instances of class c_a found after querying s in combination with x"

The larger we choose the test set, the subset I'_q of I_q, the more reliable the measures for precision and breadth. However, the number of queries increases with the number of patterns found for each instance we add to I'_q. We finally calculate the score of the patterns by multiplying the individual scores: $score(s)=f_{freq} \cdot f_{prec} \cdot f_{spr}$

For efficiency reasons, we only compute the scores of the patterns with the highest frequencies. The problem remains how to recognize a (possible multi-word) instance in the snippets. For an ontology alignment setting—where the sets I_q and I_a are not to be expanded—these problems are trivial: we determine whether $t \in I_a$ is accompanied by the queried expression. For a setting where the instances of c_a are not all known (e.g. it is not likely that we have a complete list of all books written in the world), we solve this problem in two stages. First we identify rules per class to extract candidate instances. Thereafter we use an additional query to verify if a candidate is indeed an instance of class c_a.

Instance Identification

A separate problem is the identification of terms in the text. An advantage is that we know the place in the text by construction (i.e. either preceding or following the queried expression). A disadvantage is that each class requires a different technique to identify its instances. Especially terms with a less determined format, such as movie titles, are hard to identify. We therefore design recognition functions f_i for each class.

For these functions f_i, we can adopt various techniques from the fields of (statistical) natural language processing in general and information extraction in particular. A regular expression that describes the instances of class c_i can be a part of the function f_i. The reader may also think of the use of part of speech tagging (Brill, 1992), N-gram models (Manning & Schütze, 1999; Downey, Broadhead, & Etzioni, 2007), off-the-shell named entity recognizers (Zhou & Su, 2002) or shallow parsers (Lin, 1998). We note that the HTML-markup can be of use as well, since terms tend to be emphasized, or made ‘clickable’.

After extracting a term, we can perform an additional check to find out whether the extracted term is really an instance of the concerning class. We perform this check with the use of a search engine. We query phrases that express the term-class relation. Again, these phrases can be constructed semi-automatically. Hyponym patterns are candidates as well for this purpose (Hearst, 1992, 1998; Cimiano & Staab, 2004). A term is to be accepted as instance, when the number of hits of the queried phrase is at least a certain threshold. For example, we query the phrase ‘Cities such as Eindhoven and’ to check whether ‘Eindhoven’ is indeed an instance of the class City. When we use such a check function, we can allow ourselves to formulate less strict recognition functions f_i. That is, false instances that are accepted by f_i, are still rejected as an instance by the use of the check function.

Sketch of Algorithm

Per relation, we maintain a list of instances that already have been used in a query in combination with the patterns expressing this relation. Initially, these lists are thus empty. The following steps of the algorithm are performed until either some stop criterion is reached, or until no new instances or instance-pairs can be found.

- **Step 1:** Select a relation p_k on $c_{k,0} \times c_{k,1}$ and an instance v from either $I_{k,0}$ or $I_{k,1}$ we have not yet used in a query.
- **Step 2:** Combine the patterns expressing p_k (e.g. 'starring') with v (e.g. '*David Hasselhoff'*) and send these queries ('*starring David Hasselhoff'*) to the search engine.
- **Step 3:** Extract instances from the snippets using the instance identification rules for the class applicable.
- **Step 4:** Add the newly found instances to the corresponding instance set and add the instance-pairs found (thus with v) to $T'_{(k,0),(k,1)}$.
- **Step 5:** If there exists an instance that we can use to formulate new queries, then repeat the procedure.

Note that instances of class $c_{k,0} = c_{l,1}$ learned using the algorithm applied on relation p_k on $c_{k,0} \times c_{k,1}$ can be used as input for the algorithm applied to some relation p_l on $c_{l,0} \times c_{l,1}$ to populate the sets $I'_{l,0}$ and $T'_{(l,0),(l,1)}$.

Experimental Results

In this section, we discuss some experiments we conducted with this method. In Section 2.6, we investigate whether the learned patterns are indeed intuitive, by learning a list of relation patterns expressing the broader-narrower or hyponym relation. Section 2.6 handles the use of learned patterns to populate an ontology on restaurant chains and the countries where they can be found, while we populate a movie ontology in Section 2.6. Finally, we discuss the identification of a ranked list of historical persons and their biographical information in Section 2.6.

Learning Effective Hyponym Patterns

We are interested whether the effective surface text patterns are indeed intuitive formulations of some relation p_k: $c_q \times c_a$. As a test-case, we compute the most effective patterns for the hyponym relation using a test set with names of all countries.

Our experiment was set up as follows. We collected the complete list of countries in the world from the CIA World Factbook (footnote: http://www.cia.gov/cia/publications/factbook). Let I_a be this set of countries, and let I_q be the set { 'countries', 'country' }. The set T_k consists of all pairs (a,'countries') and (a, 'country'), for a $\in I_a$. We apply the surface text pattern learning algorithm on this set T_k.

The algorithm identified almost 40,000 patterns. We computed f_{spr} and f_{prec} for the 1,000 most frequently found patterns. In Table2, we give the 25 most effective patterns found by the algorithm. Focusing on these patterns, we observe two groups: 'is a' and hyponym patterns as identified by Hearst (1992).

The hyponym patterns 'like' and 'such as' show to be the most effective. This observation is useful, when we want to minimize the amount of queries for hyponym patterns.

Expressions of properties that hold for each country and only for countries, for example the existence of a country code for dialing, are not trivially identified manually but are useful and reliable patterns.

The combination of 'is a', 'is an' or 'is the' with an adjective is a common pattern, occurring 2,400 times in the list. In future work, such adjectives can be identified in the snippets using a Part of Speech tagger (Brill, 1992) or a shallow parser (Lin, 1998 ; Marneffe, MacCartney, & Manning, 2006).

A Restaurant Ontology

The Text Retrieval Conference (TREC) question answering track in 2004 contains list question, for example 'Who are Nirvana's band members?' (Voorhees, 2004). We illustrate the use of our ontology population algorithm in the context of such list-question answering with a small case-study.

Table 2. Learned hyponym patterns and their scores given in descending order of effectiveness

pattern	freq	prec	spr

is a sovereign (country)	48	0.69	89
or any other (countries)	87	0.58	58
(countries) namely	58	0.44	109

Note that we do not consider the processing of the question itself in this research.

Inspired by one of the questions (‘What countries is Burger King located in?’), we are interested in populating an ontology with restaurants and the countries in which they operate. We identify the classes ‘country’ and ‘restaurant’ and the relation ‘located in’ between the classes.

We hand the algorithm the instances of ‘country’, as well as two instances of ‘restaurant’: ‘McDonald’s’ and ‘KFC’. Moreover, we add three instance-pairs of the relation to the algorithm. We use these pairs and a subset $I'_{country}$ of size eight to compute a ranked list of the patterns. We extract terms consisting of one up to four capitalized words. In this test we set the threshold for the number of hits for the queries with the extracted terms to 50. After a small test with names of international restaurant branches, this seemed an appropriate threshold.

The algorithm learned, besides a ranked list of 170 surface text patterns (Table 3), a list of 54 instances of restaurant (Table 4). Among these instances are indeed the names of large international chains, Burger King being one of them. Less expected are the names of geographic locations

Table 3. Top learned patterns for the restaurant-country relation

pattern	prec	spr	freq
c_a restaurants of c_q	0.24	15	21
c_a restaurants in c_q	0.07	19	9
c_a hamburger chain that occupies			
villages throughout modern day c_q	1.0	1	7
c_a restaurant in c_q	0.06	16	6
c_a restaurants in the c_q	0.13	16	2
c_a hamburger restaurant in southern c_q	1.0	1	4

and names of famous cuisines such as ‘Chinese’ and ‘French’. The last category of false instances found that have not be filtered out, are a number of very common words (e.g. ‘It’ and ‘There’).

We populate the ontology with relations found between Burger King and instances from country using the 20 most effective patterns. The algorithm returned 69 instance-pairs with countries related to ‘Burger King’. On the Burger King Web site[5] a list of the 65 countries can be found in which the hamburger chain operates. Of these 65 countries, we identified 55. This implies that our results have a precision of 55/69 = 80% and recall of 55/65 = 85%. Many of the falsely related countries—mostly in Eastern Europe—are locations where Burger King is said to have plans to expand its ‘empire’.

Populating a Movie Ontology

For this case study, we have constructed a small partial ontology on the movie domain. It is defined as O'_{movie}= ((Director, Actor, Movie),({‘Steven Spielberg’,‘Francis Ford Coppola’}, {}, {}),(‘acts-in(Movie,Actor),director-of(Movie,Director)),({}, {})).

We thus only identify three classes, of which only the class Director has instances. Using our method, we want to find movies directed by these directors. The movies found are used to find starring actors, where those actors are the basis of the search for other movies in which they played, etc. The process continues until no new instances can be found.

Relation patterns. This small ontology contains two relations, acts in and director of. For these relations, we have manually selected the sets of patterns: {“[Movie] starring [Actor]”, “[Actor] and [Actor]”} and {“[Director]’s [Movie]”, “[Movie], director: [Director]”}.

Instance identification. We identify a term as a Movie title, if it is placed in a text between quotation marks (Geleijnse & Korst, 2005; Sumida, Torisawa, & Shinzato, 2006). Although this may seem a severe restriction, in practice we can permit to loose information contained in other formulations since each query-result gives much redundant information. So, if a movie title is placed between quotation marks just once in the search results, we are able to recognize it.

A person’s name (instances of the classes Director and Movie) is to be recognized as either two or three words each starting with a capital. Another feature of the recognition function is the use of lists with taboo words. If a taboo word is contained in an expression, we ignore it. We use a list of about 90 taboo words for the person names (containing words like ‘DVD’ and ‘Biography’). For the movie titles we use a much shorter list, since movie titles can be much more diverse. We have constructed the taboo word lists based on the output of a first run of the algorithm.

We check each o the extracted candidate instances with the use of one of the following que-

Table 4. Learned instances for restaurant

Chinese	Bank	Outback Steakhouse
Denny's	Pizza Hut	Kentucky Fried Chicken
Subway	Taco Bell	Continental
Holywood	Wendy's	Long John Silver's
HOTEL OR	This	**Burger King**
Japanese	West	Keg Steakhouse
You	BP	Outback
World	Brazil	San Francisco

Louis XV	Greens	Red Lobster
Good	It	There
That	Mark	Dunkin Donuts
Italia	French	Tim Hortons

ries: ''The movie [*Movie*]'', ''[*Actor*] plays'', or ''[*Director*] directed''. A candidate is accepted, if the number of search results to the query exceeds a threshold. After some tests we choose 5 as a threshold value, since this threshold filtered out not only false instances but most of the common spelling errors in true instances as well.

Formulation of queries. The relation patterns lead to the following set of queries: {''[Director]'s'', ''[Movie] starring'', ''[Movie] director'', ''starring [Actor]''}. We have analyzed the first 100 snippets returned by the search engine after querying a pattern in combination with an instance.

Results

We first ran the algorithm with the names of two (well-known) directors as input: Francis Ford Coppola and Steven Spielberg. Afterwards, we experimented with larger sets of directors and small sets of beginning directors as input.

An interesting observation is that for this case study the output can be independent of the input sets. That is, when we take a subset of the output of an experiment as the input of another experiment, the outputs are the same, modulo some small differences due to the changes in the search results over time.

We have found 7,000 instances of the class Actor, 3,300 of Director and 12,000 of Movie. The number of retrieved instances increases, about 7%, when 500 query results are used instead of 100.

Precision. When we analyze the precision of the results, we use the data from the Internet Movie Database (IMDb) as a reference. An entry in our ontology is accepted as a correct one, if it can be found in IMDb. We have manually checked three sequences of 100 instances (at the beginning, middle and end of the generated file) of each class. We estimate a precision of 78%. Most misclassified instances were misspellings or different formulations of the same entity (e.g. ''Leo DiCaprio'' and ''Leonardo DiCaprio'').

In the future, we plan to add post processing to recognize these flaws. We can analyze the context (e.g. when 2 actors act in the same set of movies) and use approximate string matching techniques to match these cases.

Likewise, we have also analyzed the precision of the relations. We estimate the precision of the relation between movie and director around 85%, and between movie and actor around 90%.

Recall. The number of entries in IMDb exceeds our ontology by far. Although our algorithm performs especially well on recent productions, we are interested how well it performs on classic movies, actors and directors. First, we made lists of all Academy Award winners (1927-2005) in a number of relevant categories, and checked the recall (Table 5).

IMDb has a top 250 of best movies ever. The algorithm found 85% of them. We observe that results are strongly oriented towards Hollywood productions. We also made a list of all winners of the Cannes Film Festival, the 'Palme d'Or'. Alas, our algorithm only found 26 of the 58 winning movies in this category.

Extracting Information on Historical Figures

The second case study aims at extracting a long list of historical persons and in addition extracting for each of them biographical information such as nationality, period of life, and profession. Using this additional information, we can create sublists of e.g. 17th-century Dutch painters. The information extraction is carried out in two phases. First a long list of historical persons is extracted, and secondly, additional information on these persons is gathered.

Relation Patterns and Query Formulation

It has been observed by e.g. (Ravichandran & Hovy, 2002) that a surface pattern as ''Wolfgang Amadeus Mozart ('' is very successful to determine the year of birth of in this case Mozart, as the open bracket will be often followed by the period of life of the person (in this case: 1756-1791). We decided to use this observation but in a different fashion (Korst, Geleijnse, De Jong, & Verschoor, 2006). Instead of looking for the year of birth of a given person, we use year intervals that possibly relate to the lifetime of a person to find historical persons. More precisely, we issued all year intervals ''($y_1 - y_2$)'' as queries, with $y_1 \leq [1000 \ldots 1990]$, $y_2 - y_1 \leq [15 \ldots 110]$, and $y_2 \leq 2005$. In other words, we search for persons who were born during the last millennium and who died at an age between 15 and 110. Note that, in this way, we will only find persons that already passed away.

Instance Identification

For each of these issued queries, we scan the at most 1000 snippets that the search engine returned. In each of these snippets, we determine the first occurrence of the queried pair of numbers. Since search engines ignore non-alphanumeric characters, the queried pair of numbers may also occur as

Table 5. Recall of academy award winners

Category	Recall
Best Actor	96%
Best Actress	94%
Best Director	98%
Best Picture	87%

y_1, y_2 or as y_1 / y_2. If the queried pair of numbers is in the intended context ($y_1 – y_2$), i.e. if they are surrounded by brackets and separated by a hyphen, then the words directly preceding this first occurrence are stored for later analysis, to a maximum of six words. In this way, we obtain for each queried pair of numbers up to 1000 short text fragments that potentially contain person names. In addition, for each of the stored text fragments, we remove potential pre- and suffixes that normally cannot be part of a name. For example, we delete all words that precede a full stop (except when preceded by a single capital letter), a colon, or a semicolon. In addition, of words consisting of upper-case letters only we transform the upper-case into lower-case letters, except for the first one (with some specific exceptions concerning ordinal numbers of kings, queens, etc., composite names including hyphens or apostrophes, and Scottish and Irish names). This results in a set of candidate names.

The *check* phase consists of two filtering steps: one to filter out non-person names and one to filter out multiple variants of a single person name. These steps are next discussed in more detail. Not all text fragments we have found in the extraction phase will be person names. Typically, historic periods, art styles, geographic names, etc. can also directly precede a time interval. Table 6 illustrates the difficulties in discriminating between person names and other text fragments. We note that West Mae probably refers to the person name *Mae West* and that *Napoleon Hill* refers to a person as well as to a geographic location in the state Idaho (USA).

To filter out non-person names, we first constructed from dedicated Web sites a long list of the most common first names (boy's and girl's names). If a text fragment starts with such a name, then this is a strong indication that the text fragment is a person name. In addition, we constructed a long list of suspect words that typically do not occur in person names, as follows. From the many snippets that we gathered with the year interval queries we extracted all words, counting how often they occur with a capital and without a capital. If a word occurs most often without a capital, and it is not a special word as 'van', 'de', or 'la', then it is added to the long list of suspect words. We next apply a rule-based approach using these lists of first names and suspect words to filter out text fragments that probably do not relate to person names. In addition to filtering out non-person names, we also want to filter out multiple occurrences of the same person name. These occurrences are caused by variations in spelling of names and errors in the lifetimes. To this end, we carried out the following filtering steps.

1. **Keeping only the last name/lifetime variants that occur most often.** For each last name/lifetime combination, we often find different variants of first names preceding it. For example, Bach (1685–1750) is preceded by, e.g., Johann Sebastian, JS, and Johann S. Of all these variants we only store the

Table 6. Some examples to illustrate the difficulties in discriminating between persons names and other text fragments

Person Name	Non-Person Names
Art Blakey	Art Deco
West, Mae	West Virginia
Amy Beach	Miami Beach
HP Lovecraft	HP Inkjet
Napoleon Hill	Napoleon Hill

one that is found most often, i.e., the variant that occurs most often in the text fragments we found in the 1000 snippets returned on query ‘’(1685–1750)”.

2. **Filtering out small variations in name.** If two names have exactly the same lifetime and the edit distance (Gusfield, 1997) between these full names is less than a given threshold, then only the variant that is found most often is kept. As threshold we use an edit distance of two.
3. **Filtering out single errors in lifetimes.** If two names are completely identical but their lifetimes differ in only the year of birth *or* the year of death, then only the variant that is found most often is kept.

Experiments indicate that in this step we reduce the candidate set of names by approximately 25%.

Ordering Persons by Fame

To order the persons by fame, we use the number of hits (the ‘Google Page Count’ GPC) as our measure of fame. Now, the question is which query we should issue to the search engine to determine the GPC of a person. The query should be neither too general nor too specific. A single person is often identified in different ways, e.g. Johann Sebastian Bach, JS Bach, JOHANN SEBASTIAN BACH and Bach, Johann Sebastian all refer to the same person. The last variant is called an *inversion*. The latter two variants can be transformed into the first variant by substituting upper-case characters by lower-case ones and by adjusting the order of first and last names. Complicating factors in the identification of inversions are *(i)* that a comma between last name and first names is sometimes omitted and *(ii)* that many first names also occur as last names. An additional complication is that the first names sometimes vary per language (e.g. Charles vs. Karel). To achieve that we are less sensitive to these variants, we use the following query to determine the GPC:‘’[last name] ([year of birth]–[year of death])”

For kings, queens, popes, etc., we use the Latin ordinal number as last name. In this way Charles V (1500–1558), Carlos V (1500–1558), and Karel V (1500–1558) are all covered by query ‘’V(1500–1558)”. Note that we assume the combination of last name and lifetime to be specific enough to uniquely identify historical persons.

Extracting Additional Information

The first phase, described above, resulted in a large list of historical persons that was ordered using GPC as measure of fame. For further details on this list we refer to (Korst, Geleijnse, De Jong, & Verschoor, 2006). In the next phase, we extracted additional information, such as gender, nationality, and professions. Also, we tried to retrieve related images and a few one-liners that already give a brief impression of how the person gathered fame. We extracted additional information for the top 10,000 of the list of historical persons that we obtained in the first phase. We next briefly describe how we gathered this additional material.

To acquire additional information, we again issued queries of the type ‘’Albert Einstein was’’, i.e., we used the full name of a person followed by the word was, where we restrict ourselves to English language pages. From the snippets returned, we extracted complete sentences that contain the query. Hence, if only a fraction of a sentence was given in a snippet, then this fraction was simply ignored. These sentences were next used to identify specific words that indicate gender, nationality and professions.

Determining gender. We simply counted words that refer to the male gender, namely the words he, his, son of, brother of, father of, man and men. Likewise, we counted words that refer to the female gender, namely the words she, her, daughter of, sister of, mother of, woman, and women. We simply assigned the gender with the highest count.

Table 7. The 20 persons born between 1880 and 1889 with the highest GPC

Born In [1880–1889]		
James Joyce (1882-1941)	Ireland	author
Bela Bartok (1881-1945)	Hungary	composer
Pablo Picasso (1881-1973)	Spain	artist
Anton Webern (1883-1945)	Austria	musician, composer
HL Mencken (1880-1956)	United States	author, journalist
Niels Bohr (1885-1962)	Denmark	scientist, physicist
Adolf Hitler (1889-1945)	Germany	leader
Amedeo Modigliani (1884-1920)	Italy	artist, painter
Agustin Barrios (1885-1944)	Paraguay	musician, composer
Le Corbusier (1887-1965)	Switzerland	architect
John Maynard Keynes (1883-1946)	United Kingdom	economist
Ludwig Wittgenstein (1889-1951)	Austria	philosopher
Igor Stravinsky (1882-1971)	Russia	composer
TS Eliot (1888-1965)	United Kingdom	poet
Franz Kafka (1883-1924)	Czech Republic	author
Franklin D. Roosevelt (1882-1945)	United States	president
Marc Chagall (1887-1985)	Russia	painter, artist
Martin Heidegger (1889-1976)	Germany	philosopher
Kahlil Gibran (1883-1931)	Lebanon	poet, philosopher,...
Heitor Villa-Lobos (1887-1959)	Brazil	composer

Determining nationality. We extracted for each country from the CIA World Factbook Web site the country name (in conventional short form) and the corresponding adjective that indicates nationality, e.g. ‘Belgium’ and ‘Belgian’. In addition, for some countries we added a number of additional terms relating to parts of the country, such as ‘Flemish’ for Belgium and ‘English’, ‘Scottish’, and ‘Welsh’ for the United Kingdom. To determine the nationality, we count for each country the number of word occurrences in the set of sentences, and simply assign the nationality with the highest count. So far, we did not consider country names of countries that do no longer exist, such as Prussia.

Determining professions. As for gender and nationality, we now simply count how often each of these profession names occur in the sentences. However, instead of only selecting the one with the highest count, we here want to be able to retain multiple professions. For that reason, we select the ones that have at least a count of $0.5 \cdot c_{max}$, where c_{max} is the score of the highest scoring profession, ordered by decreasing count.

Results

To give an impression of the results that we obtained in this case study, we present three tables. Table 7 gives the top of the persons born in the period 1880—1889, Table 8 gives the top of the persons that has as their highest scoring profession either artist or painter. For more details and examples we refer to (Korst, Geleijnse, De Jong, & Verschoor, 2006) and (Geleijnse and Korst, 2007).

Considering Table 9, we observe that Thomas Young is given the American nationality, while

Table 8. The 25 artists/painters with the highest GPC

Artists/Painters		
Leonardo da Vinci (1452–1519)	Italy	artist, scientist,...
Pablo Picasso (1881–1973)	Spain	artist
Vincent van Gogh (1853–1890)	Netherlands	artist, painter
Claude Monet (1840–1926)	France	artist, painter,...
Pierre-Auguste Renoir (1841–1919)	France	painter
Paul Gauguin (1848–1903)	France	painter
Edgar Degas (1834–1917)	France	artist, painter,...
Paul Cezanne (1839–1906)	France	painter, artist
Salvador Dali (1904–1989)	Spain	artist
Henri Michaux (1899–1984)	Belgium	artist, poet
Gustav Klimt (1862–1918)	Austria	painter, artist
Peter Paul Rubens (1577–1640)	Belgium	artist, painter
Katsushika Hokusai (1760–1849)	Japan	painter
Amedeo Modigliani (1884–1920)	Italy	artist, painter
JMW Turner (1775–1851)	United Kingdom	artist, painter
James McNeill Whistler (1834–1903)	United States	artist
Rene Magritte (1898–1967)	Belgium	artist, painter
Henri Matisse (1869–1954)	France	artist
Rembrandt van Rijn (1606–1669)	Netherlands	artist, painter
Edouard Manet (1832–1883)	France	artist, painter
Herm Albright (1876–1944)	—	artist, engraver,...
Marc Chagall (1887–1985)	Russia	painter, artist
Edvard Munch (1863–1944)	Norway	painter, artist
Wassily Kandinsky (1866–1944)	Russia	artist, painter
Francisco Goya (1746–1828)	Spain	artist, painter

he is from the United Kingdom. This is due to the fact that Thomas Young is a common name, thus many of the sentences starting with ‘Thomas Young was’ actually refer to different persons. Unfortunately, Marie Curie is not in this sublist. The only reason is that her only profession that is retained was ‘scientist’. Otherwise, she would have ranked between Rutherford and Feynman. For the same reason, Robert Hooke would have ranked between Heisenberg and Volta, and Robert Wilhelm Bunsen would have ranked between Hahn and Curie. The first profession of Sir David Brewster is judge, resulting from the phrase “Sir David Brewster was afraid that the members could scarcely judge ...”.

Recall. To get an impression of the performance of our algorithm, we estimate the recall by choosing a diverse set of six books containing short biographies of persons whom we would expect to find in our list. For each of these books, we determined for the persons that could potentially be found by our algorithm (i.e., the persons who are born in the intended time period and have died). Of these 1049 persons, 1033 were present in our list, which is a fraction of 0.98. For further details on the chosen books we refer to Korst, Geleijnse,

Table 9. The 40 physicists with the highest GPC

Albert Einstein (1879–1955)	scientist, physicist
Isaac Newton (1642–1727)	scientist, mathematician, physicist
Galileo Galilei (1564–1642)	astronomer, physicist, scientist
Niels Bohr (1885–1962)	scientist, physicist
Lord Kelvin (1824–1907)	physicist, scientist, mathematician
Christiaan Huygens (1629–1695)	astronomer, scientist, mathematician, physicist
Michael Faraday (1791–1867)	chemist, scientist, physicist
Georg Christoph Lichtenberg (1742–1799)	physicist, author, mathematician, astronomer
James Clerk Maxwell (1831–1879)	physicist
Max Planck (1858–1947)	physicist
Ernest Rutherford (1871–1937)	scientist, physicist
Richard Feynman (1918–1988)	physicist
Hermann von Helmholtz (1821–1894)	scientist, physicist
Werner Heisenberg (1901–1976)	physicist
Alessandro Volta (1745–1827)	physicist
Wolfgang Pauli (1900–1958)	physicist
Sir Arthur Eddington (1882–1944)	scientist, physicist, director, author
Heinrich Hertz (1857–1894)	scientist, physicist, explorer, author, researcher
Wilhelm Conrad Roentgen (1845–1923)	scientist, physicist, director
Paul Dirac (1902–1984)	physicist
Andre Marie Ampere (1775–1836)	physicist, mathematician
Joseph John Thomson (1856–1940)	scientist, physicist, explorer
James Prescott Joule (1818–1889)	scientist, physicist
Ludwig Boltzmann (1844–1906)	physicist
Thomas Young (1773–1829)	physicist, physician, scientist
Ernst Mach (1838–1916)	philosopher, physicist
Evangelista Torricelli (1608–1647)	physcist, mathematician
Charles Augustin Coulomb (1736–1806)	engineer, physicist, scientist
Otto Hahn (1879–1968)	chemist, physicist
Pierre Curie (1859–1906)	physicist
Otto von Guericke (1602–1686)	scientist, inventor, physicist
Sir David Brewster (1781–1868)	judge, physicist
William Henry Bragg (1862–1942)	physicist
Thomas Kuhn (1922–1996)	philosopher, physicist, historian
George Gamow (1904–1968)	physicist
Sadi Carnot (1796–1832)	physicist, engineer
Gustav Theodor Fechner (1801–1887)	physicist, psychologist, philosopher
Joseph Swan (1828–1914)	chemist, inventor, physicist
Louis de Broglie (1892–1987)	physicist
Augustin Fresnel (1788–1827)	inventor, physicist, engineer

De Jong, & Verschoor, 2006). We observe that the recall is close to one, for each of the six books, even for a more specialized topic as 17th century Dutch painters. Of the total 108 of these painters mentioned in one of the books, 106 were found. We note that of the 16 persons that did not appear in our list, there were 4 persons for which the books could not provide the lifetime. For the recall of the additional information, we observe that for the 10,000 persons that we considered all were given a gender, 77% were given a nationality, and 95% were given one or more professions.

Precision. All kinds of imperfections can still be observed in our list of historical persons, such as remaining inversions, missing parts of a name, and errors in lifetimes, although each of these occurs relatively infrequently. We concentrate on estimating the fraction of names that do not relate to persons. The corresponding precision that is obtained by the algorithm has been estimated as follows. We selected three decennia, namely 1220-1229, 1550-1559 and 1880-1889, and analyzed for each the candidate persons that were 'born' in this decennium. For the first two decennia we analyzed the complete list, for decennium 1880-1889 we analyzed only the first 1000 as well as the last 1000 names. This resulted in a precision of 0.94, 0.95, and 0.98, respectively. As the decennium of 1880-1889 resulted in considerably more names, we take a weighted average of these results. This yields an estimated precision for the complete list of 0.98 (Korst, Geleijnse, De Jong, & Verschoor, 2006). Regarding the precision of the property *lived-in*, we make the following observations. Considering the list of 450,000 potential instances that our algorithm found for this property, we observe that 235 were found with a GPC of at least 10,000 and 2450 were found with a GPC of at least 1000. Clearly, the probability that instances with a high GPC contain spelling errors in person name or lifetime is quite low, since accidental spelling errors in the last name or in the lifetime will result in a low GPC. Indeed, we found that the accuracy of our results was better than that of the information in some of the books.

Biographical entries. To get a better impression of the quality of the biographical entries, we manually checked 50 persons, evenly distributed in the top-2500. Of these 50 persons, we observed that gender, nationality and professions were all correct for 38 persons. No errors in gender were detected in any of the 50 persons. For three persons the nationality was not found. All nationalities found proved to be correct. For two persons, all given professions were wrong. For eight others, one or more given professions were incorrect, but usually the professions with the highest count were correct.

COMMUNITY-BASED KNOWLEDGE MINING

In this second part of the chapter, we focus on more subjective knowledge. For example, we are interested the most appropriate genre for a musical artist, using the collective knowledge of the Web community. As such knowledge is not only expressed (directly) within sentences, we discuss two alternative methods to find relations, apart from the pattern-based method described in the previous part. Since we focus on subjective knowledge, multiple relations are possible, e.g. Madonna may both be a Rock and a Pop artist. We therefore assign a score for each of the relations found. For example, the aim is to find a higher score for the relation between ABBA and Disco than between ABBA and Dead Metal. As the focus is on scoring relations, we assume the classes to be complete. This second part of the chapter is organized as follows. In Section3.1 we formally define the problem, while Section3.2 discusses the three alternative methods to categorize instances. In Section3.3 we discuss a similar method to find relatedness between the instances. The found relatedness scores can be used to improve the categorization (Section3.4). Experiments in two domains are discussed in Section3.5. Finally we conclude this part of the chapter in Section4.

Problem Description

We want to map a complete set of instances of class c_a- artists or items such as movies or paintings—to a set of categories: instances of class c_s. Given are two sets of instances I_a of size N and I_s of size M. Hence, I_a is a set with instances such as paintings, or artists. The set I_s contains categories like movements in art or genres. We are interested in a mapping m: $I_a \rightarrow I_s$.

Definition. We call a category m(b) *most appropriate* for b if a domain expert would select m(b) from the set I_s as the category best applicable to b.

Problem 1. Find for each b $\in I_a$ the most appropriate m(b) $\in I_s$.

Problem 2. Find for each pair of instances of c_a, *(b,c)* a score Γ*(b,c)* expressing the extent of relatedness between b and c.

We use co-occurrences of instances in I_a and categories in I_s (e.g. Johnny Cash and country) on the Web to extract such information to compute a preliminary mapping. Additionally, we assume that related instances in I_a often share a category in I_s. We compute distances between instances using Web co-occurrences in order to identify the nearest neighbors for each instance. The preliminary mapping of each artist and its nearest neighbors are combined into a final mapping m.

Three Classification Methods

In this section, we present three methods to classify instances in I_a using Web data. The first method is based on analyzing the total numbers of co-occurrences of instances in I_a and categories in I_s on the Web. To retrieve this data we again use a state of the art search engine. An important drawback of this page count method is that it has a high *Google Complexity*, i.e. it requires many queries to a search engine, namely $O(N \cdot M)$. For large sets this can be problematic, since search engines currently allow only a limited amount of automated queries per day (Cafarella, Downey, Soderland, & Etzioni, 2005). Moreover, the number of hits can fluctuate over time (Véronis, 2006), which hampers the reuse of old hit counts. We present two alternative methods that do not suffer from these drawbacks.

We are interested in a mapping m', based on co-occurrences of elements in I_a and I_s. In Section3.4 we combine this mapping m' with a distance matrix between related instances in I_a to find a definite mapping *m*.

Page-Count-Based Mapping (PCM)

To obtain the mapping m' we perform a query "b","g" for each pair (b,g) $\in I_a \times I_s$. Per query, we extract the estimated number of *hits* co(*b*,*g*).

co(*b*,*g*)='the number of hits for query "b", "g"'

We assume that the order of the terms *b* and *g* in the query does not effect the number of hits, thus we assume co(*b*,*g*)= co(*g*,*b*).

This Page-Count-based Mapping (PCM) is simple and intuitive. If we are for example interested in categorizing music artists into genres, we analyze the number of hits to queries for combinations of the names of the artist and each genre. Assuming Johnny Cash to be a country artist, we expect that more documents contain both the terms *Country* and *Johnny Cash* than *Reggae* and *Johnny Cash*.

Per b $\in I_a$ we could map the g $\in I_s$ with the most hits. However, we observe that frequently occurring categories in I_s have a larger probability to be mapped to any instance in I_a. For example, the query '*Pop*' results in 8 times more hits than the query '*Disco*'. Although we consider *Boney M* as a *disco-act*, the query *'Boney M, pop'* gives twice the amount of hits as *'Boney M, disco'*. This observation leads to a normalized approach, inspired by the theory of pointwise mutual information (Manning & Schütze, 1999; Downey et al., 2005). For $b \in I_a$ and $g \in I_s$, we define a scoring function S(b,g) as follows.

$$S(b,g) = \frac{co(b,g)}{1 + \sum_{c \in Ia} co(c,g)} \tag{1}$$

In the denominator we add 1 to the sum of all co-occurrences with g to avoid dividing by 0.

Having computed the scores for all pairs, we select a preliminary mapping *m'* for each $b \in I_a$. Per instance we select the category $g \in I_s$ with the highest score S.

$$m'(b) = \arg\max_{h \in 1g} S(b,h) \tag{2}$$

Using PCM we thus need to perform N · M queries.

Pattern-Based Mapping (PM)

The Pattern-based Mapping (PM) is based on occurrences of terms in phrases on the Web. We observe combinations of terms in phrases that express the relation we are interested in. For example, if we are interested in the relation between music artists (in I_a) and their genres (in I_s), an appropriate phrase that links terms of the two could be *'[artist] is one of the biggest [genre] artists'*. We can identify these patterns automatically by using a training set of related instances and categories; see (Ravichandran & Hovy, 2002; Geleijnse & Korst, 2006) and Section2.3 of this chapter. Learning patterns can be done with *O*(N) queries.

We use combinations of a pattern and an instance or a category as a query to the search engine. For example, if we have the pattern *''[genre] artist such as [artist]''*, we use *''artist such as''* in queries in combinations with all names of genres and artists. We use this pattern e.g. both for the query *''Country artists such as''* and for the query *''artists such as Prince''*. In the snippets found with the first query, we identify instances in I_a, while in the results for the second query we search for categories in I_s related to Prince. These queries provide access to relevant data. From the snippets returned by the search engine, we thus identify the elements of either I_a or I_s to measure the number of co-occurrences of the pairs. Hence, using PM co(b,g) is defined as follows.

co(b,g) = 'number of occurrences of *b* by querying patterns with *g*' + 'number of occurrences of *g* by querying patterns with *b*'

Using PM we only need *O*(M+N) queries. We use the same scoring function S(b,g) as given in (1) to obtain a preliminary mapping as given in (2).

Document-Based Mapping (DM)

In the Document-based Mapping (DM) approach we collect the first *k* URLs of the documents returned by the search engine for a given query. These *k* URLs are the most relevant for the query submitted based on the ranking used by the search engine (Brin & Page, 1998).

In the first phase of the algorithm, we query all instances in both I_a and I_s and collect the top *k* documents for each of the queries. For instances in I_a, we retrieve each document using the URLs found by the search engine. We count the occurrences of the categories in I_s (thus the names of the categories) in the retrieved documents for the intermediate mapping *m'*. From the documents retrieved with a category $g \in I_s$, we similarly extract the occurrences of instances in I_a.

The documents obtained using DM are the most relevant for each element $b \in I_a$. For the artists queried we expect biographies, fan pages, pages of museums, entries in database sites and so on. The categories in I_s (e.g. the genres or styles) mentioned in these pages will most probably reflect the genre of the artist queried.

Thus the co-occurrences function is here defined as follows.

co(b,g) = 'number of occurrences of *b* in documents found with *g*' + 'number of occurrences of *g* in documents found with *b*'

The co-occurrences of elements in I_a and I_s again are used for an intermediate mapping using the same scoring function. This method also requires only *O*(M+N) queries. However, additional data communication is required since for each query up to *k* documents have to be downloaded instead of using only the data provided by the search engine.

Finding Related Instances

We use the same three co-occurrence-based methods to compute the relatedness between elements in I_a. We consider instances in I_a to be related, when they frequently co-occur in the same context. In Section3.4, we use this information in a final mapping *m* between elements in I_a and I_s. Per pair (b,c) $\in I_a \times I_a$ we compute the score $\Gamma(b,c)$, similar to the score S in (1).

$$r\left(b,c\right) = \frac{co\left(b,c\right)}{\sum_{x,x\neq} co\left(x,c\right)} \tag{3}$$

Again, we do not use a majority voting to prevent frequently occurring instances to be strongly related to many other instances.

In PCM we combine the names of two artists into a query and extract the number of *hits*. Using this method this phase requires N^2 queries.

If we use PM to obtain the numbers of co-occurrences of instances in I_a, we can specify the nature of the relatedness. For example, for instances of the class pop artist, we can solely be interested in artists who have played together. A pattern such as *''[pop artist] recorded a duet with [pop artist]''* could be suitable for this purpose. This phase of the method consists of $k \cdot$ N queries (with *k* the number of patterns). In the documents obtained with the DM method we only expect occurrences of other terms in I_a that are strongly connected with the b $\in I_a$ queried. For DM no additional queries have to be performed in this phase, since we can reuse the documents obtained in the first phase.

Combining Results in Final Mapping

We use the assumption that related instances in I_a often share the same category. We investigate whether the use of relatedness between instances in I_a helps to improve to the precision of the mapping *m'*. We combine the scores Γ with the preliminary mapping *m*' as follows. Per b $\in I_a$, we inspect *m*' to determine the category that is assigned most often to b and its *n* closest related instances. We thus expect that the most appropriate category *g* for b is most often mapped by *m*' among b and its nearest neighbors.

Per instance b $\in I_a$, we construct an ordered list B(n) with b and its *n* nearest neighbors

$B(n) = (b_0, b_1, \ldots, b_n)$
with $b = b_0$ as its first element and
$\Gamma(b,b_i) \geq \Gamma(b,b_{i+1})$, for i < 0

For a final mapping *m* of instances b $\in I_a$ to a category in I_s, we inspect the most occurring category mapped by *m'* to b and its *n* nearest neighbors.

$$m\left(b,n\right) = \arg\max_{h \in Is} \sum_{c \in B\left(n\right)} \tau\left(c,h\right)$$

with

$$\tau(c,h) = 1 \quad \text{if } m'(b_i) = h$$
$$= 0 \quad \text{otherwise}$$

Table 10. patterns for artist—artist relation

"like I_{224} and I_{224}"
"such as I_{224} and I_{224} "
"including I_{224} and I_{224} "
"for example I_{224} and I_{224} "
"namely I_{224} and I_{224}"
" I_{224} and I_{224} "
" I_{224} I_{224} and other"

If two categories have an equal score, we select the first occurring one. That is, the category that is mapped by *m'* to b or to the artist most related to b.

Experimental Results

We evaluate the methods discussed in this part of the chapter as follows. First, we evaluate the instance-similarity scoring using the three methods PM, DM and PCM. These similarities are used in the subsequent part to classify musical artists into genres. Finally, we repeat this experiment on a different domain to classify painters into art movements.

Musical Artist Similarity

We use the common test set I_{224} of 224 artists, equally divided over 14 genres as defined by Knees et al. (2004)[6] to evaluate the computed artist similarities Γ(b,c). We consider two artists to be similar, if they share a genre in the test set. In these experiments, we only evaluate precision. If for an b $\in I_a$ no mapping or related instance could be found, we consider the result to be incorrect.

For PCM we added the extra term music for finding co-occurrences of the artists. For example the terms Bush and Inner Circle co-occurred a lot on the Web, due to American politics. By adding the term music we restrict ourselves to documents handling music.

Figure 1. Precision for classification of the 224 musical artists

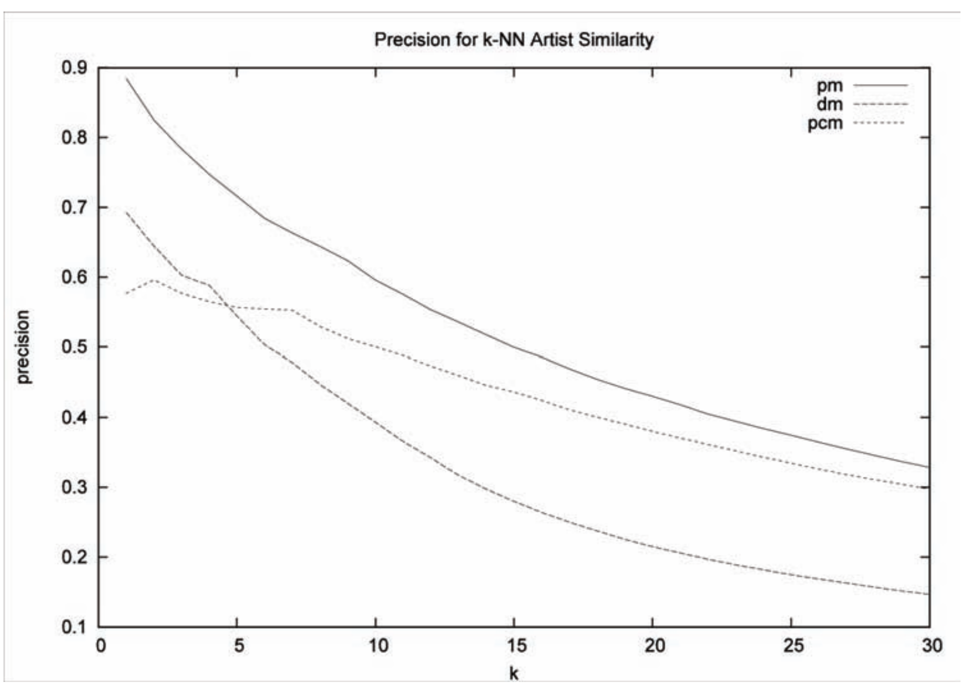

Table 11. The patterns for the artist-genre relation

"I_g (artists OR bands OR acts OR musicians) like I_{224}"
"I_g (artists OR bands OR acts OR musicians) such as I_{224}"
"I_g (artists OR bands OR acts OR musicians) for example I_{224}"
"I_{224} and other I_g (artists OR bands OR acts OR musicians)"

Since we are not interested in the nature of the relatedness between artists, for PM we selected general enumeration patterns (Table 10) to obtain co-occurrences.

Figure 1 shows the average precision of the similarity of the artists and their *k*-NN for the sets of 224 artists. We can conclude that the pattern based method PM gives good results and outperforms both DM and PCM. For smaller values of *k* the method most inefficient in the number of queries is outperformed by both DM and PM. The performance of DM drops quickly due to the fact that only few related artists are mentioned among the best ranked pages for the queried instances.

Musical Artist Genre Tagging

In this experiment, I_{224} is again the set of all artist names in the list composed by Knees, Pampalk & Widmer (2004). This list consists of 14 genres, each with 16 artists.

To find a mapping between I_{224} and the set of genres I_g, the genres mentioned in the list are not all suitable for finding co-occurrences. For example, the term *classical* is ambiguous and *Alternative Rock/Indie* is an infrequent term. We therefore manually rewrote the names of the genres into unambiguous ones (such as *classical music*) and added some synonyms. After collecting the numbers of co-occurrences of artists and genres, we summed up the scores of the co-occurrences for synonyms. Thus, for each artist *b* the number of co-occurrences with the terms *Indie* and *Alternative Rock* are added to the co-occurrences of *b* with the genre *Alternative Rock/Indie*. Motivated by the results in (Schedl et. al, 2005), for PCM we used the allintitle option in the artist classification experiment.

For PM we selected for the genre-artist relations the patterns in Table 11 from a list of patterns found expressing this relation.

For all three methods, we reuse the computed artist similarities.

In Table 12 the performance of the preliminary mapping can be found for the three methods (n = 0). We were able to map all artists to a genre. Co-occurrences between genres and artists thus could be found using PCM, PM as well as DM. The latter performs best. With respect to the preliminary mapping, the method with the smallest amount of Google queries performs best. The data found on the best ranked documents is thus reliable.

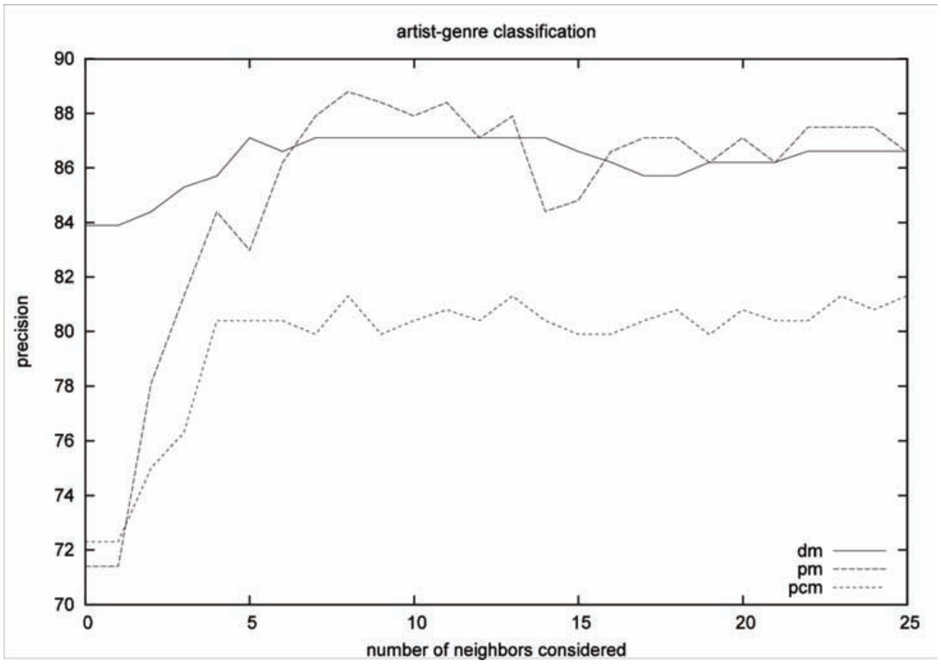
Using DM only few related artists can be found on the documents visited. This leads to a stable performance for the final mapping when expanding the list of related artists (Figure 2). That is, we only consider artists that co-occur at least once. Contrary to especially PCM, large numbers of *n* do not deteriorate the precision.

The performance of the pattern-based method strongly improves by considering related artists, the best performance is obtained for n = 8. All methods perform best for values of n between 5 and 13. The *Rock n' Roll* artists proved to be the

Table 12. Precision (%) without related artists and best precision per method

method	n=0	best	(corresponding *n*)
PCM	71.4	81.3	(13)
PM	72.2	88.8	(8)
DM	83.9	87.1	(5)

Figure 2. Precision (%) for classification of the musical artists



most problematic to categorize. The artists in the genres *classical*, *blues* and *jazz* were all correctly categorized with the best scoring settings. With the supervised music artist clustering method discussed in (Knees et al., 2004) a precision of 87% was obtained using complex machine learning techniques and a relatively large training set. In (Schedl et al., 2005) a precision of up to 85% was obtained using $O(N^2)$ queries. We can conclude that our simple and unsupervised method produces similar results. Moreover, we compute a classification of artists into genres instead of clusters of artists.

Painter Movement Classification

For this experiment, we constructed a list of painters I_a and a list of movements I_s in art using Wikipedia and map the two. From Wikipedia we extracted a set I_a of 1,280 well-known painters from the article *List of painters* and a set I_s of 77 movements in art from *List of art movements*[7]. We tested the performance of the algorithm on the subset of 160 painters who could be extracted from the Wikipedia pages describing movements (e.g. from the page on Abstract Expressionism). The other 1,120 painters are either not mentioned on the pages describing styles or are mentioned on more than one page. However, when computing similarities between the painters, we take all 1,280 painters into account.For the elements of I_s in this test no synonyms were added. For fairness, we excluded pages from the domain wikipedia.org in the search queries.

For PM, we selected learned patterns for the mapping between the elements in I_a and I_s. For learning, we used instance-pairs outside the test set. The best scoring patterns can be found in Table 13. For the relation between the instances in I_a, these patterns found were mostly enumeration patterns, e.g. *''including b and''*. The complete details of both experiments and the patterns used in PM can be found on the Web (**footnote**http://gijsg.dse.nl/Webconmine/). Due to the rareness of

Table 13. Best scoring learned patterns for painter—movement relation

“I_a I_s”
“I_s I_a”
“I_a and other I_s”
“I_a and I_s”
“I_a tog initiativ til I_s”
“I_a and the I_s”
“I_a surrealism I_s”
“I_a synthetic I_s”
“I_s artist I_a”
“I_a express I_s”
“I_a of the I_s”
“I_a uit de I_s”
“I_a experimenting with I_s”
“I_a arte I_s”
“I_s painter I_a”

some of the painters and names of movements, we did not use any additional terms in the queries for DM or PCM.

In Table 14 the performance of the preliminary mapping *m’* can be found for the three methods (n = 0). The experiments show that in general the use of related instances improves the classification (see Table 14 and Figure 3). It shows again that the methods with the lowest Google Complexity thus PM and DM perform better than PCM.

Although in the painter-movement experiment the number of categories identified (77) is much larger than in the previous experiment (16), the performance of PM and especially DM is still good. The results of PCM indicate that when the precision of the intermediate mapping is low (35%), the use of related instances does not improve the results. In this experiment we even observe a deterioration of the performance. Here DM clearly outperforms PM. This can be explained by the fact that using PM considerably less painter-movement pairs could be extracted. We expected the recall of PM to increase when applying stemming on the names of movements and the texts extracted (Porter, 1997). Although the number of pairs extracted slightly increases, the precision does not improve (Table 14).

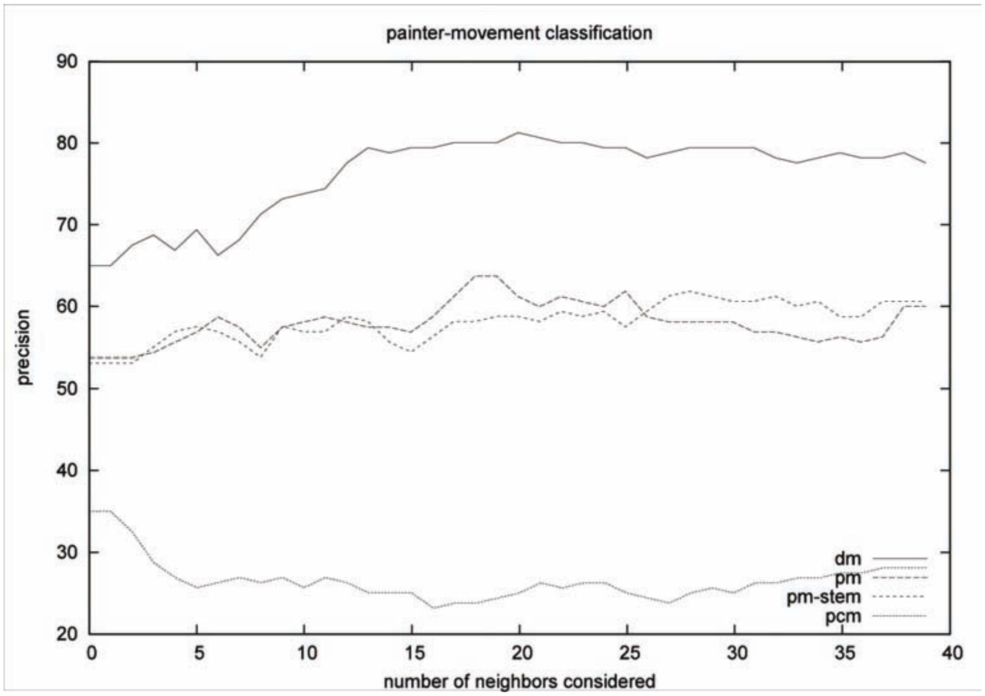
CONCLUSION

In Section 2 we have presented a framework algorithm for ontology population using queried expressions to mine factual information. We combine patterns expressing relations and an instance of a class into queries to generate highly usable search engine snippets. From these snippets we simultaneously extract instances of the classes and instance pairs of the relations. The results of the experiments are convincing. When submitting effective queries, the snippets provide enough data to populate an ontology with good recall and precision. The method is simple and easily adaptable to different domains. In the second part, we have discussed three alternative methods PCM, PM and DM to obtain co-occurrences of terms using a search engine. These methods are applied to gain a preliminary mapping between instances such as artists or painters and categories such as genres or art-movements. The distance between related instances is used to obtain a more reliable mapping. The three alternatives used have a different complexity with respect to the number

Table 14. Precision (%) without related instances and best precision per method

	Painter-Movement		
method	N = 0	best	(corresp. n)
PCM	35.0	35.0	(0)
PM	53.8	63.8	(18)
DM	65.0	81.2	(20)
PM-STEMMING	53.2	61.9	(28)

Figure 3. Precision (%) for classification of the painters



of queries to a search engine. The method using patterns and the one using complete documents are linear in the number of items in the sets of instances and categories, where the page-count-based mapping is quadratic. This distinction is important for classifying large sets of instances, since search engines allow only a limited amount of automated queries per day. We can precisely classify artists to genres, where the most efficient methods with respect to the Google complexity perform best. A second experiment consisted of the mapping of painters to their movements. This experiment underlines that the document-based and pattern-based method outperform the query-expensive method based on the number of search engine hits. We showed that simple and unsupervised methods can be used for a reliable classification. Using related instances indeed helps to improve the classification of instances. The experiments show an increase of the performance in both experiments. However, the Google count based method in painter classification shows that this additional step deteriorates the precision, if the classification is very unreliable.

FUTURE RESEARCH DIRECTIONS

We have shown that the pattern based approach in general gives access to highly relevant snippets. For future work, it is the process of identifying the instances within the snippets that needs further research.

The creation of precise rules is a laborious task, especially since each class requires its specific set of rules. The experiments in Part I showed that the challenge lies in the improvement of the precision of the recognition rules and the check functions.

The use of check functions based on enumeration of candidate instance has potential. Part II showed us that enumeration patterns are reliable to identify related instances. Now, if our ontology contains the instances *KFC* and *McDonald's,* we can formulate enumeration queries containing these instances and candidate instances. Fore example, the enumeration *'KFC, Chinese and McDonald's'* is not found by Google, where *'KFC, Burger King and McDonald's'* gives 31 hits.

With the known instances and the instances learned using the rules, we can automatically create an annotated corpus. This annotated corpus can be used to train a named entity recognizer. Such a named entity recognizer should be robust and consider only the local context of the named entities, as the snippets contain incomplete sentences. Approaches using only fully parsed sentences are therefore less usable. Memory-based learning (Daelemans & van den Bosch, 2005) is a technique that does not abstract from the learned instances. Moreover, only a small window of words is taken into account. If the information is redundantly available within the snippets, this technique may lead to satisfactory results.

The use of named entity recognizers based on machine learning also gives the possibility to compare the various approaches. When we collect the downloaded snippets, this comparison can be made on the same data.

With respect to the community-based data, in this chapter we assumed that the mapping was functional, i.e. only one category could be assigned to an instance. However, in some tasks multiple categories can apply to an instance. We therefore want to adapt the system such that multiple categories accompanied with a confidence mark can be assigned to an instance, analogue to the Web 2.0 concept of social tagging (O'Reilly, 2005). Moreover, methods can be exploited to learn other words related to some category, e.g. with the $tf \cdot idf$-approach (Knees et al., 2004; Manning & Schütze, 1999).

ADDITIONAL READING

A solid introduction into the field of statistical natural language processing is the book by Manning and Schütze (1999). It is well readable as it contains both chapters discussing elementary mathematical notions and the linguistic essentials. Sentence parsing, word sense disambiguation and term identification are some of the introduced topics that are relevant for Web Information Extraction. An alterative is (Jurafsky & Martin, 2000).

In (2005) McCallum introduces the problem of information extraction to a broad audience. A list of relevant papers is provided for further reading as well as a number of URLs of tools for information extraction, for instance the GATE framework (Cunningham, Maynard, Bontcheva, & Tablan, 2002). Not named by McCallum, but nevertheless interesting is the KnowItAll project by the group of Oren Etzioni (2005). In one of the KnowItAll papers, (Downey et al., 2005), the redundancy of information on the Web is exploited to identify instances on the Web without supervision. The same paradigm is the basis of (De Boer et al., 2007) where relations between painters and art movements are learned.

In the second part of this chapter, the tagging of items is discussed. Previous work addresses the 'auto tagging' of Weblogs (Brooks & Montanez, 2006; Balog, Mishne, & De Rijke, 2006; Mishne, 2007). Given a post on a Weblog, the question is which tags are appropriate labels for this post.

In this work, we used a set of rules to identify the instances within the texts. However, when an annotated training set is available (or can be created), instances can also be recognized using machine learning. In (Manning and Schütze,1999) a thorough introduction to Hidden Markov Models is given and their applications in natural language processing. Daelemans and Van den Bosch use Memory-based learning to identify named-entities (2005). A broad overview of machine learning and pattern classification techniques can be found in (Duda, Hart, & Stork, 2000).

The above mentioned approaches are based on statistical techniques. In (Blackburn & Bos, 2005) and (Bunt & Muskens, 2000) models are discussed where the meaning of a texts can be represented in a formal language. A field closely related to Information Extraction is Question Answering. Given a corpus, answers to questions like 'Who is the Mayor of San Francisco?' need to be answered. In (Ravichandran, 2005; Dumais, Banko, Brill, Lin, & Ng, 2002) question answering systems are presented that use the Web as a corpus.

APPENDIX: QUESTIONS FOR DISCUSSION

1. Why is it hard to compare two different approaches in ontology population from the Web? (The obtained query results differ.)
2. Alike the SW languages (introduced in chapter X by Cardoso), we consider binary relations between instances. Show that these can also be used to express associations with more than two instances.
3. Suppose that you have created an ontology with the class City. How would you identify instances of this class? How about instances of the class Texan Cities, cities within the state Texas?
4. What is the Google Complexity of the ontology population method applied on the movie ontology in Section 2.6?
5. In the second part of the Chapter, relations are given a score. How would you model this scoring using the SW languages, cf. (Mika, 2007)?
6. Suppose you are interested in a ordered list of all American presidents from George Washington to George W. Bush. Formulate classes and relations that describe this information demand. What would be appropriate patterns to populate this ontology?
7. KnowItAll is a system that extracts information from the Web from both structured sources (e.g. tables and lists) and unstructured Web texts. Can you think of information demands where the extraction of data from tables is less usable?

ABSTRACT

The following chapter focuses on the problem of the proper definition of non-functional properties and methods that may be applied in order to estimate their values. First of all, a reader is familiarized with the concept of non-functional properties and different views on the quality of Web services. Then, selected approaches to obtain values of non-functional properties are presented. The focus of attention is Web services profiling that seems to be one of the most promising methods to perform this task. The framework presented in this chapter was implemented and tested within the EU Adaptive Services Grid project.

DOI: 10.4018/978-1-60566-042-4.ch005

INTRODUCTION

The paradigm of service-oriented architecture (SOA) is currently one of the most popular approaches followed by modellers and IT developers in order to build IT systems. The potential of SOA is being strengthened by the growing popularity of Web services technology. Web services allow for encapsulation of business functionalities provided using IT infrastructure and easy integration with other systems via standard communication protocols. Globalization, along with a tendency to outsource some activities, boosts the exploitation of Web services in enterprise applications.

One of the essential elements needed to ensure the success of Web services (as well as Semantic

Web services) technology is a proper Web service description to be used not only in order to invoke a Web service, but also to discover it and perform composition. The common agreement is that a Web service should be represented by its surrogate, describing its functional, non-functional, and behavioural characteristics. The functional features focus on what a Web service does, the non-functional ones on how it does it, and the behavioural ones inform us which parties are involved in the process of service provisioning. Whereas, there seems to exist a common agreement on how the description of the functional and behavioural properties of a service should look like and its role in Web services' interactions; there is still an ongoing discussion about the scope and the methods that should be used to express the non-functional side of a Web service.

Within the last few years, a number of different approaches to define non-functional properties and quality of service (QoS) models for Web services have been proposed. Each of them defines a different set and understanding of non-functional properties as well as QoS features. Yet, as shown in this chapter, these initiatives are still not mature enough as they focus mostly on the technical aspects of a Web service and, in most cases, disregard the business ones. Another problem that appears, once the model of non-functional properties is defined, relates to the methods that can be utilized in order to obtain values of defined properties. Various techniques to carry out this task were proposed. They differ in terms of reliability, trustworthiness, as well as the issue of continuous provisioning of up-to-date values of parameters.

The following chapter focuses on the problem of definition of non-functional properties and methods to estimate their values. The special focus is assigned to the Web services profiling, being, in our opinion, one of the most promising methods to perform this task. The chapter is organized as follows. First, we present our understanding of non-functional properties and quality of service. In the following section, the methods to compute values of non-functional properties are discussed. The following section outlines current methods to compute values of non-functional properties. Then, the concepts of service profiling, service profile, and its elements are presented. Moreover, in this section we also describe the technical details of service profiling system implemented within the Adaptive Services Grid project. Finally, the summary follows.

NON-FUNCTIONAL PROPERTIES OF WEB SERVICES

To fully exploit the advantages of Web services technology, as indicated in the introduction section, their proper description is required. The common agreement is that a Web service should be represented by its surrogate, providing information on its functional (what a Web service does), non-functional (how it does it), and behavioural characteristics (which parties are involved in the process of service provisioning). However, before the initiatives in the area of Web services description are presented, differences between a service and a Web service, being crucial for our further discussion, need to be mentioned.

A service is usually defined as a provision of value in some domain (Preist, 2004) or seen as a business activity that often results in intangible outcomes or benefits (Baida, Gordijn, Omelayenko, & Akkermans, 2004). Let us consider an example of a person who wants to buy a book on knowledge representation published by Springer. The service this person is looking for is the provisioning of books with the specified constraints. A provision is in fact independent on how the supplier and provider interact (Lara & Olmedilla, 2005), that is, it does not really matter at this point whether the requester goes to a bookshop or uses the Amazon.com portal to buy the book of interest.

A Web service in turn may be defined as a computational entity accessible over the Internet (using particular standards and protocols) (Preist, 2004). The focus is assigned here to the way that the requester and provider interact with each other (Lara & Olmedilla, 2005). In the considered example with a book, a bookshop (e.g., Amazon.com) may provide a component accessible via Web service standards (i.e., a Web service) to request the book. Therefore, a Web service is a technical implementation, an interface to a real-world service defined as a certain activity undertaken on behalf of a certain entity. Final users are in fact more interested in the real service they get, rather than in the interface itself. Hence, Web services may be considered as two inseparable parts: a technical interface (described using Web service description language (WSDL) and a real (business) functionality (described by other means) the interface provides access to.

The above perception of a service and Web services entails a question what kind of a Web services description is required for the needs of interactions with and between Web services. A Web service is an interface used to request the actual provisioning of a real-world service fulfilling the requester needs. Therefore, for example, in order to discover a Web service and use it to request a required service, the technical description of a Web service (the interface) is of course crucial but not sufficient. What is also indispensable is the description of a real world service and non-functional properties of both a service and a Web service. The way consumers interact with traditional services and their requirements regarding their description are a result of social and economic interactions that have been taking place for many years. If Web service providers do not consider this fact, they will fail. Therefore, a Web service description should adhere to the well-established requirements of the consumers and cover not only functional, but also non-functional properties (NFP) of a service (Abramowicz, Kaczmarek, & Zyskowski, 2006), (Abramowicz, Kaczmarek, Kowalkiewicz, & Zyskowski, 2005).

Reviewing the Web service description initiatives at least two things should to be taken into account, namely the scope of such a description and formalism used to express it. There are many initiatives in the area of service description. The earliest ones, like WSDL (W3C, 2007), focused mainly on purely technical details needed in order to invoke a Web service (such as its interface, ports, bindings, etc.) and were expressed using XML notation. Then the other initiatives, like UDDI registry (UDDI, 2004), adding few non-functional properties to the Web service description followed. Finally, the semantic initiatives like OWL-S (W3C, 2004), WSMO (Roman et al., 2006), or SAWSDL (Farrel & Lausen, 2006) expressed using the logic-based language, such as, for example, Web services modeling language (WSML) or resource description framework (RDF) and trying to also capture information on the real-world service standing behind the Web service interface were undertaken.

Having a look at those initiatives, one thing may be quite easily noticed. There seems to exist a common agreement on how the description of the functional properties of a service should look like and its role in Web services interactions. However, there is still an ongoing discussion on the scope and methods that should be used to express the non-functional side of a service.

Functional properties represent the capability of a Web service. These properties are mainly related to the input and output parameters as well as constraints/a state of the world before and after service execution. Therefore, in most cases either the functionality is expressed as only information on inputs and outputs (like in WSDL where input and output parameters required by a service are defined) or as the semantically annotated quadruple IOPE (inputs, outputs, preconditions, and effects) in OWL-S or pre- and post-conditions defined within WSMO. The functional properties are used mainly for the needs of discovery and composition of Web services. The mechanisms operating on all of the above mentioned formalisms are already implemented and work more or

Table 1. A few exemplary non-functional parameters

Parameter name	Definition
execution price	an amount of money that needs to be paid to the service provider for service execution
latency time	a round-trip time between sending a request and receiving a response
average (maximum) response time	an average (maximum) time needed for the packet of control data to get to the provider's server (where the service is executed) and then return to the requester
robustness	ability of a service to act properly if some of the input parameters are missing or incorrect
availability	probability whether a service is capable of processing the client's request or not at a certain time
charging method	by execution unit, subscription, or by data chunk size and so forth.
payment method	information on method of payment (wire transfer, etc.)

less efficiently in various projects (Abramowicz, Haniewicz, Kaczmarek, & Zyskowski, 2006a; Kuster, Koenig-Ries, Stern, & Klein, 2007; Liu, Peng, & Chen, 2006).

In turn, the non-functional properties play a crucial role in almost all service interactions (to mention only selection, discovery, and filtering). Non-functional properties of a service may be defined as anything that exhibits a constraint over the functionality (O'Sullivan, Edmond, & Hofstede, 2002). In fact, non-functional parameters are distinctive criteria for the success of businesses offering their services using Web services technology. They allow differentiating between Web services offering the same (or quite similar) functionality, as, in most cases, service substitutes differ when it comes to the values of specific non-functional properties. Their role became even more important, as nowadays Web services are not only used internally, but also support collaboration between various organizations. In consequence, final users (especially business users) desire to know in advance the real quality and non-functional properties of external services they are to use.

The non-functional parameters may be represented as qualitative and quantitative measures of a Web service (or a service). The nonquantitative ones include security or transactions, whereas quantitative ones include such attributes as cost or time. NFP should of course include business constraints and interservice dependencies, if possible. However, different types of services require different properties describing them and which properties are necessary depends on the domain, intended use, and users' requirements. If services are to be used to automate B2B and B2C models, they have to be described in a proper manner and meet specific business requirements. The table below presents a few exemplary non-functional parameters.

The non-functional model for Web services is still under development. Each of the already mentioned service description initiatives or standards like WSDL, UDDI, OWL-S, WSMO, or SAWSDL treats non-functional properties in different ways. No non-functional properties can be expressed using WSDL. A list of non-functional parameters provided by UDDIs includes only some attributes such as, for example,: provider name, service name, and category. In turn, OWL-S and WSMO take into account a wider range of NFP (than, for example, UDDIs), including not only information on service providers, but also some performance-related information, such as execution time and so forth. The short overview of non-functional aspects supported by the selected Web services description approaches is presented in the following table.

The lack of a real support (i.e, languages, methodologies, tools) for non-functional properties may result from the following issues (Eenoo,

Table 2. Overview of the support of the selected Web services description approaches to NFP

Web services description	Approach to NFP
WSDL	Nonfunctional properties are neglected
UDDI	Defines a set of non-functional properties of a service provider (included in BusinessEntity) such as: address, phone number, e-mail address, and some meta data about a service as, for example, service category
OWL-S	Includes the following non-functional properties: service name, text description, quality rating, and service category; all are stored in the ServiceProfile class. The list may be extended using the ServiceParameter from the ServiceProfile class.
WSMO	It recommends a set of NFP for each element of a Web service description (e.g., contributor, creator, date, and so forth) provided by the Dublin Core Metadata Initiative. WSMO does not provide a model for the non-functional properties of a service (Toma, 2006), but there is an on-going work in this direction.
O'Sullivan's approach	(O'Sullivan et al. (2002) describe a set of the most relevant non-functional properties for Web services and their modelling. Exemplary concepts considered are as follows: service provider, locative model, temporal model, service availability, obligations, price, payment, discounts, trust, security, and so forth.

Hylooz, & Khan, 2005; Rosa, Cunha, Freire, & Justo, 2002; Toma, 2006):

- Non-functional properties are usually too abstract and most of the time they are stated informally;
- In some cases there is no clear distinction between the functional and non-functional aspects of a service;
- Non-functional properties are often considered to be represented only after the functional and behavioural have been described;
- Non-functional properties very often conflict and compete with each other (e.g., availability and performance);
- Complexity of modelling non-functional properties (difficult to formalize).

DUALITY IN WEB SERVICES QUALITY

Quality of a Web service may be defined as an extent to which a Web service provisioning process as well as delivered results meet expectations of a user. It is a subset of non-functional properties of a Web service. When considering the quality concept of Web services their dual character (the relation to the real world services) should be taken into account. Therefore, in defining quality of service one needs to consider two aspects: the quality of a Web service implementation (the interface), and the quality of a real service (available through a Web service interface). That is why a QoS concept for Web services should be divided into two separate groups, namely, quality of execution (QoE) and quality of result (QoR) as proposed by Abramowicz, Filipowska, Kaczmarek, Kaczmarek, Kowalkiewicz, Rutkowski et al. (2006). Let us consider a simple route planning service which is a part of the Adaptive Services Grid project's demonstration scenario (Noll, 2004).

QoR of this service may be defined as:

- A service provider's statement on the overall quality of the result provided by the service (low/high, etc.). It should be understood as follows. To what extent should a user trust the provided route description? Is it adequate and reliable? Does it show exactly what a user wanted? Will a user following the obtained route reach the desired destination point? Other parameters may be also considered (e.g., the route description, the resolution and colours of the image, and accuracy). These characteristics have a crucial impact on the satisfaction of

Table 3. RoutePlanning service example (Noll, 2004)

Service name	**Route Planning Service**
Description	Creates a route description for the customer's coordinates and the given attraction. The route description consists of a coloured high-resolution picture and a textual description.
Nonfunctional Properties	
Service Name	Map24RoutePlanningService
Provider Name	Map24.de
Information Quality	High
Functional Properties	
Preconditions	Location ls, Location lg
Positive Effects	RouteDescription rd, hasRoute (rd, r)

a user and are a part of the QoR concept.

- Users' feedback (assessment) understood as their satisfaction from the returned result (not from the interface through which they communicate with a service) expressed in a defined scale. However, it would be very difficult, if not impossible, to collect such information from users. They would rather provide an overall evaluation of both a service implementation and real service effects.

The QoR concept is domain specific. In fact, it is very difficult, if not impossible, to define a measure that would hold for all possible services. It is not the case with QoE, which is independent of the domain and rather easy to compute. The quality of execution relates to the underlying technology (i.e., technical and network-related aspects). The following properties may be a part of the QoE model:

- **Response latency:** Time needed for the control data to get to the service and back to the client.
- **Maximal throughput:** How many requests a provider is able to process in a given time period.
- **Execution duration:** Time needed to fulfil a user request (time between sending a request and receiving an answer).
- **Execution price:** Amount of money a user needs to pay in order to use an interface to the service.
- **Service robustness:** The ability of a service to act properly if some of the input parameters are missing or incorrect (e.g., the wrong coordinates or incorrect data types, etc.).

The following table summarizes our short discussion on the differences between the QoR and QoE concepts.

Another aspect that needs to be mentioned is

Table 4. Comparison of QoR and QoE

Quality of Result	**Quality of Execution**
Quality of a real service	Quality of an interface (WS implementation)
Domain specific	Domain independent
Very hard to measure and monitor	Rather easy to measure and monitor
In most cases has no impact on QoE	May have an impact on QoR

the difference between an execution price and a service price. A service price is the amount of money a user has to pay for a real service; for example, when using a route planning it is a price of the attraction ticket (e.g., ticket to the cinema) (it influences QoR). In this case, an execution price is the amount of money we have to pay for using the interface to book tickets, not a price of the ticket itself (it influences QoE). When buying a book at Amazon.com, the execution price is 0 (using the Amazon Web page to search and order is free), but the service price is the price of the book and the delivery costs. In case of information services (such services where output returned by a service is equal to the effect we wanted to obtain) it is rather unclear whether the price we have to pay for the information is a service price or execution price, and the classification may depend on many factors.

Most of the current initiatives aiming at providing definitions and descriptions of quality dimension address only some generic parameters (mostly network related), such as execution price and duration, availability and reliability, and so forth (Liu, Ngu, & Zeng, 2004; Menasce, 2002; Zeng, Benatallah, Dumas, Kalagnanam, & Sheng, 2003), and do not differentiate between the QoR and QoE concepts. More parameters, considering also QoR, are presented by O'Sullivan et al. (2002), but they are not widely used in practice. Moreover, QoR properties are not considered in most of the methods trying to compute the values of non-functional properties. Therefore, in the remaining part of this chapter, whenever a reference to QoS is made, it refers to those quality parameters of a service that are computable (therefore, in most cases they exclude QoR parameters). Whenever a clear differentiation needs to be made between quality of result and quality of execution, respective terms are used.

METHODS AND APPROACHES TO DERIVE VALUES OF NON-FUNCTIONAL PROPERTIES

The simplest way to derive values of NFP is to rely on service providers advertising this information. However, taking directly the values advertised by a service provider is not advisable. It requires users to trust the accuracy of the values declared by service providers. However, service providers do have an interest in overestimating NFP of their services, so a solution allowing measurement of (programmatically) the values of NFP for verification purposes is needed. Moreover, values of non functional parameters are often assumed to be constant in time and space (service location), but they may change, depending on the details of the service request, execution environment, and so forth. For example, the response time of a Web service may be less than 5 minutes during the working days, but during the weekends, it may be less than 1 minute as the interest in the particular service decreases.

To avoid the problems of accuracy of non-functional properties' values given by service providers, some other methods to derive (or verify) their values are needed (Abramowicz et al., 2005). Ran (2003) proposes a QoS model using a QoS certifier to verify published QoS criteria. The approach requires all Web services providers to advertise their services with the QoS certifier. However, this approach does not take into account the dynamism of the environment and the fact that the values of a Web service change in time. The approach does not provide, for example, methods to update the QoS values automatically and it lacks the details regarding the verification process.

Sheth, Cordoso, Miller, and Kochut (2002) propose a QoS middleware infrastructure that requires a built-in tool to monitor metrics of NFP automatically. Such an approach requires the willingness of service providers to give up some of their autonomy. It may also require service providers to cover execution costs. Moreover, if the polling interval is set to too long, the QoS will not be up-to-date. If the polling interval is set to too of a short time, it might incur a high performance overhead. A similar approach emphasizing a service reputation, is proposed by Maximilien and Singh (2002a, 2002b).

Another approach obtains information on values of QoS parameters from the users themselves. When collecting quality information from the users feedback, each user is required to evaluate QoS (and at the same time QoR) of the consumed service. The main advantage of this approach is that QoS values can be computed based on the real user experience (up-to-date runtime execution data). The main disadvantage is the fact that a user judgment is not objective; users use different definitions of quality, have different past experiences, and so forth.

In other approaches called "*a'posteriori approach*" (Casati, Castellanos, Dayal, & Shan, 2004) QoS values are solely collected through an active monitoring. The monitoring can be performed by a user, service broker or platform, dedicated QoS registry (Kuropka & Weske, 2006; Liu et al., 2004), or an already mentioned QoS certifier (Ran, 2003). The data are collected from the actual consumption of a service and therefore are accurate and objective. One avoids the necessity to install rather expensive middleware in order to constantly check large numbers of service providers. However, there is a high overhead since QoS must be constantly checked for a large number of Web services. On the other hand, the approach that relies on a third party to rate or endorse a particular service provider is expensive and static in nature.

When the service related data collection is envisioned through, for example, workflow monitoring or user feedback, another important issue is how to compute the values of quality-related parameters from the collected data. There are a few initiatives to solve the problem. One of them (Maximilien & Singh, 2004) suggests performing an analysis of past executions of atomic and composite services by using data mining and workflow log mining techniques. Moreover, some statistical methods can be applied as well (Liu et al., 2004).

Workflow management systems are a very important infrastructure for complex applications. They usually register the start and completion of activities as well as other events that occur during execution. This information is stored as workflow log files (Aalst, Zhang, Shanahas, & et al., 2003) that further are processed using workflow and process mining techniques. The goal of workflow mining is to find a workflow model on a basis of a workflow log (Aalst et al., 2003). In turn, process mining is a method of distilling a structured process description from a set of real executions (Aalst et al., 2003). Many methods to perform these tasks were developed (e.g., probabilistic workflow mining, or Petri nets [Aalst et al., 2003]) and may be successfully applied also to the Web services area.

In the next section, the Web services profiling, being an alternative method to derive the values of non-functional properties of a Web service, is presented.

WEB SERVICE PROFILING, SERVICE PROFILE, AND ITS ELEMENTS

Service profiling is a process of computation of values of non-functional properties. The main goal of service profiling is to create service profiles of atomic and composite services. A service profile may be defined as an up-to-date description of a selected subset of non-functional properties of a service. It not only characterizes a service but also allows for services comparison based on aggregated values of non-functional parameters and, in consequence, selection of a service most suited to the requirements of a user.

In order to compute the values of non-functional properties, service profiling needs first to collect information on services executions, aggregate it, and then derive required information. The raw data may come from multiple data sources. Every source has its own specific purpose and provides different information. The following possible sources of information that further feed the profiling system with appropriate data may be distinguished: service registries, monitoring data, data coming from service level agreements (SLA) storing information on contracted QoS values, feedback from service consumers about obtained service quality, and so forth.

The aim of the Web services profiling is to perform fair and open NFP computation. Therefore, as the service execution history data are the most objective and reliable source of information on the service, they are in fact the primary source of information. The Web services profiling does not perform only the core workflow mining. It analyses log files in order to obtain data needed for the profiling process, but, in addition, it takes advantage of the raw data collected from service properties defined in SLA, published by service providers, and obtained from users' feedback. For instance, it compares contracted values from SLA against these from execution. In consequence, it is possible to check to what extent the agreement between a provider and a consumer is fulfilled. Moreover, appropriate algorithms may discover which values of particular parameters are, for example, likely to be guaranteed by providers.

Service profiling is, in our opinion, a trustworthy method of service quality measurement. It does not rely on providers' declarations about quality of their services. Statistical procedures used to compute values, data coming from execution logs, and so forth, assure high reliability of results of service profiling. The information declared initially by a service provider might be verified by what is stated in SLA, being approved by its provider and then by the results of the analysis of execution data. This kind of verification increases the reliability of our mechanism and we do not need a third party to verify the correctness of the values of profile parameters as procedures are transparent and parameters precisely defined. In addition, a service profiling mechanism is generic (a number of parameters it operates on may be easy modified) and independent of the service description provided by a service provider.

Service Profile

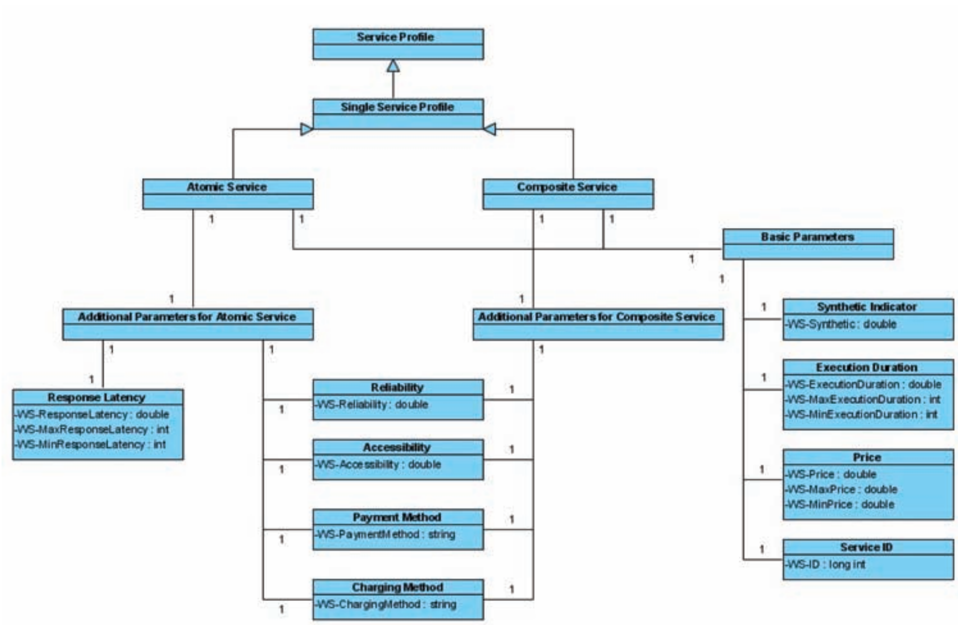
As already stated, a service profile may be defined as an up-to-date description of a subset of non-functional properties of a service. It allows for services comparison based on non-functional parameters and selection of the service most suited to the requirements of a user.

In order to create an adequate service description one needs to consider that the collected or derived data, taken into account by a service profiling mechanism, may differ in terms of its stability in time. Regarding the type of information on services, we can distinguish three main categories:

- **Static Information:** Values of service properties that do not change over time, such as name of the service, and are provided by a service provider.
- **Semistatic information:** Values of service properties that may change over time, such as quality of service and price. This information changes periodically, but not very often.
- **Dynamic Information:** Values of service properties that may be (and usually are) different in every execution of the service. It relates mainly to the network related quality of service.

From the profiling point of view, the most interesting parameters are the dynamic and semistatic ones. In addition, parameters that are estimated and finally included in a service profile may be simple reflections of service behaviour or adequately aggregated to show an overall quality of a service. Therefore, we consider two groups of non-functional properties:

Figure 1. Service profile structure - class diagram



- **Simple Properties:** Values of service properties that can be monitored on an individual level. This is mostly information presented in service level agreements. Such properties may include, for example, latency time, execution cos,t and so on.
- **Derived Properties:** Where additional manipulation is needed (performed by a service profiling system). Such properties may include reliability, availability, or, in our case, a synthetic indicator.

Our belief is that a service profile should be easily interchanged between building blocks of SOA systems. In order to allow for simple messaging and processing of profiles, we decided to represent them as XML documents. The greatest advantage of this solution is that XML schema is easily verifiable and interpretable by machines. A standardized form of a service profile makes it easy to be adapted in industrial applications.

Because of flexibility of service profiling, the set of parameters included in a profile may vary due to different quality parameters considered in different IT systems. The exemplary structure of a profile (as seen in Figure 1) was derived based on the requirements defined in the already mentioned ASG project.

The excerpt of a service profile schema is presented in the Listing 1. Please note that for some parameters, average, minimal, and maximal values are determined. These values may be helpful when a user precisely expresses the user's needs on quality parameters. Therefore, a user may specify that the user is looking for a service where parameters meet accurately expressed criteria.

Additionally, a service profiling system may offer provider profiles that show how, in general, services of a given provider behave. They may be useful to represent the overall quality of services provided by a concrete provider. These profiles are more quality-oriented, whereas service profiles are more performance-oriented. In this case, quality orientation means that time-related QoS parameters are less important than the fact whether a given service was accessible or produced expected results.

Figure 2. Listing 1: Excerpt of exemplary service profile schema

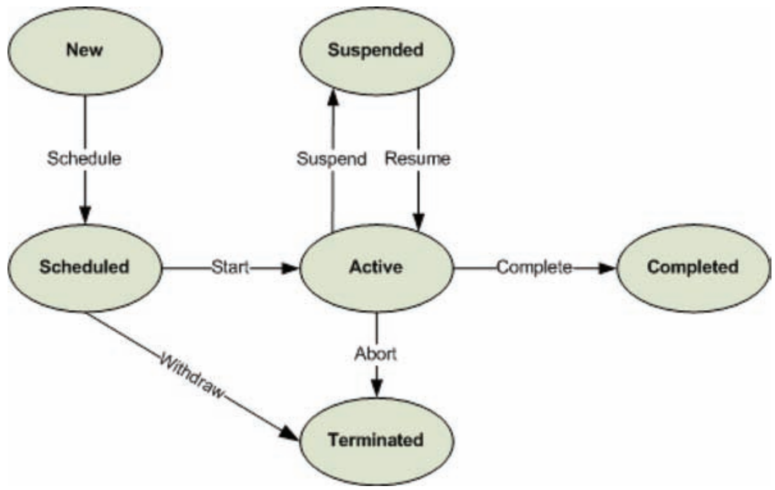
Service Profile Computation

The most popular information sources for service profiling are execution logs. These log files usually have a strictly defined structure (Aalst et al., 2003), so the automated processing of them is feasible and algorithms are rather straightforward. For example, the execution duration may be easily counted as a difference between end time and start time of a service execution (these values are stored in the log file). Of course, to compute the values of other parameters other methods may be required. For instance, in order to compute the value of a reliability parameter, a profiling system needs to keep track of service execution states. In our approach, we consider the finite state machine of Web service transitions as shown in the Figure 3.

Figure 3. Types of Web services events. Based on Aalst et al. (2003)



Therefore, it is possible to determine the number of started services that were completed. Thus, the assessment of reliability parameter is not a problem. A similar approach is used for accessibility parameter computation. For more details please refer Kowalkiewicz, Ludwig, Kaczmarek, and Zyskowski (2005). In the Table 5 we present an exemplary set of non-functional properties and outline methods of their computation.

When creating a service profile the time horizon is taken into account. A user may need a particular instance of a service only once in a given point of time or may need to use the service a few times in a given time period. Therefore, the horizon of the prognosis should be considered. In the first case, short-time information about a service is important, and in the second case, more attention should be paid to the long-term behaviour of a service, taking into account also more historical data.

Another challenging issue is the set of non-functional parameters that should be used to describe composite services and the way to compute values of these parameters. The possible solutions may be found presented by Liu et al. (2004), Maximilien and Singh (2004), and Zeng et al. (2003). They suggest using a similar set of attributes, as for atomic services and computing their values using statistical methods.

Composite service profiles are the aggregations of atomic service profiles. A description of a composite service profile is very similar to a service profile, because it treats a composite service like an atomic one. That is why the structure of its profile does not differ significantly from the profile of an atomic service. However, the values of some

Table 5. Some parameters of service profile and their computation methods

Parameter name	Computation method
Execution duration	Difference between end and start time of service execution
Accessibility	Number of successful invocations divided by all the invocations in a given time period
Reliability	Number of successful executions divided by all of the executions in a given time period
Price	Average price in a given period of time
Synthetic indicator	Statistical aggregation of all considered parameters denoting an overall quality of a service

parameters are computed as statistical measures based on characteristics of atomic services included in the composed service. Moreover, not all parameters that are computed for an atomic service profile are included in composite service profiles. For example, the response latency value is only computable for atomic services.

In order to compute a value of quality parameters of a composite service we can proceed twofold:

- The execution log mining may be performed in order to compute values of parameters using methods similar to these for atomic services;
- A composite service execution plan may be used to compute *hypothetical value* of quality parameter. Such plans are usually described using business process execution language for Web services (BPEL4WS) language. First, the average values for each atomic service included in the composition are computed, then the plan is analysed, the critical path is identified, and the hypothetical value is computed. For instance, the execution duration of the composite service is computed as a sum of execution durations of services being on the critical path. Other calculations include analysis of workflow patterns, determination of how many times services were executed (in case of loops), and so forth. Details about such computation are given by Kowalkiewicz et al. (2005).

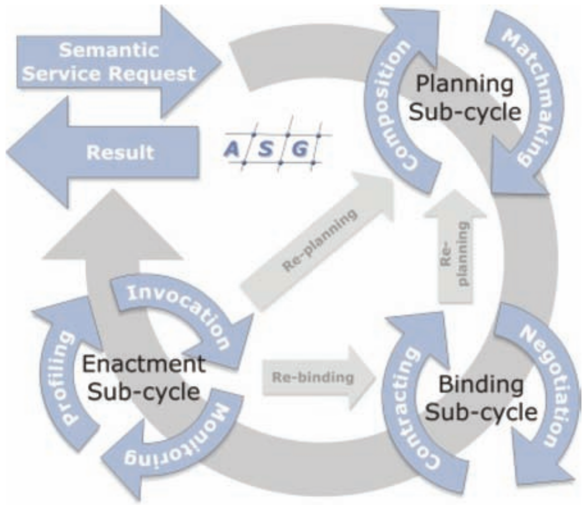
It can be very interesting to rank services according their quality. In order to do that, a method that would allow one to compare objects (in our case, services) with regard to different properties that describe these objects was defined. Our decision was to take advantage of the multiple criteria analysis (MCA) that ideally fitted to our needs. We used the MCA method to rank services based on their quality attributes. This ranking was created by computing a synthetic indicator reflecting the overall service quality. Then, it was possible to compare the values of synthetic indicators of several services and make a choice between them. The detailed description of MCA and the procedure to compute the value of a synthetic indicator is described by Abramowicz, Haniewicz, Kaczmarek, and Zyskowski (2006b).

Dynamic Service Profiling in the Adaptive Services Grid Project

Taking into account the issues discussed in the previous section, the architecture of the service profiling system should consist of at least a few components. It should include the repository that will store the data gathered by the system and should have component(s) responsible for communication with the data sources. Moreover, it should provide interfaces that allow all interested parties to ask queries. Finally, it should have the profiling mechanism, responsible for analysing the data and deriving/computing the values of parameters, to be included in a service profile.

As an example of the architecture of service profiling system, the dynamic service profiling component of the Adaptive Services Grid project, may be presented. The main goal of the ASG project (Kuropka & Weske, 2006) was to develop a proof-of-concept prototype of a platform for adaptive services discovery, creation, composition, enactment, as well as negotiations and service profiling. In order to support the above-mentioned interactions, the ASG platform and mechanisms require the ability to differentiate and compare different services and service substitutes (services having the same functionality). There are some requirements that need to be met in order to make the service differentiation feasible. First, the non-functional parameters must be taken into account, as every customer perceives the service not only from the side of what functionality it gives, but is also interested in non-functional properties of the service. The next issue is to deliver a QoS model

Figure 4. Service delivery process in the ASG. ©Krause, 2005 (used with permission)

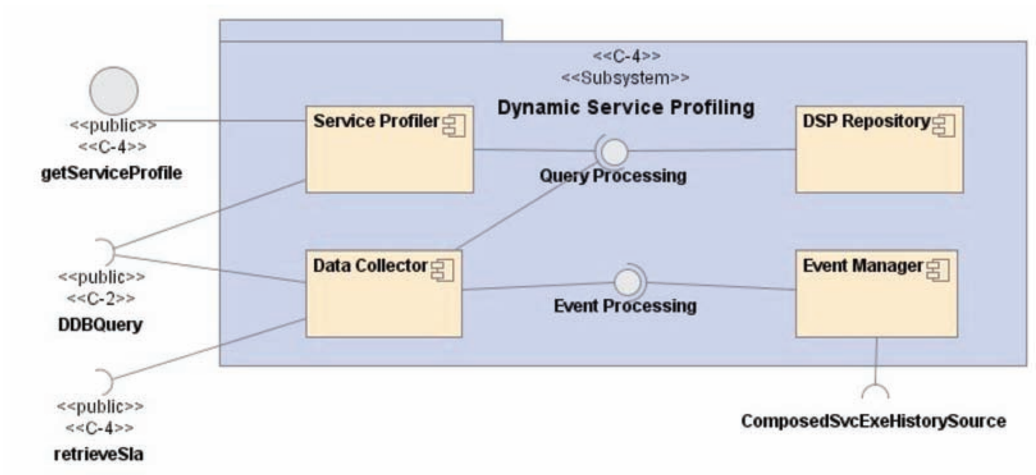


that everybody would accept. Such a standardized QoS model is the first step to the agreement on monitoring mechanisms, common SLAs, and other elements that should be a part of every mature marketplace. The last challenge is to create adequate description of a service that will give a user hints about the distinctive features of service substitutes. Thanks to the monitoring, it should be possible to analyse the information coming from service executions, SLA violations, and so forth. Based on the execution data and users' preferences, it is reasonable to create a service profile which reflects QoS values of a given service in a considered time horizon. Moreover, the user should be capable of ranking these profiles and choosing the most suitable Web service. Such a mechanism is implemented in the Adaptive Services Grid platform (Kuropka & Weske, 2006) using a dynamic service profiling (DSP) mechanism. The ASG service delivery process is presented in the figure below.

The architecture of a dynamic service profiling (see Figure 5) system, being a part of the entire ASG platform, consists of a few components (Abramowicz, Kaczmarek, Kowalkiewicz, & Zyskowski, 2006):

- Data collector, which is responsible for collecting data (by either a push or a pull method) from different sources, processing them, and saving properly aggregated to the DSP repository.
- Service profiler, which is responsible for deriving QoS attributes to answer requests. The Service profiler creates an up-to-date profile of a service (or a provider), whenever it receives a query. Two types of queries may be distinguished: a request for a profile of composed service, taking time horizon into consideration; and a request for profiles and a ranking of a set of atomic services, taking time horizon into consideration. When creating profiles, the service profiler uses the following data about services: data from the provider's declaration (service registry), and values of service attributes form the past execution (DSP repository). In order to create a profile, the appropriate values of characteristics, depending on the prognosis horizon, are computed. Then, based on the computed values a synthetic indicator for a service is created. As an interaction with a user is not

Figure 5. Architecture of DSP system



implemented, default user preferences are used. After computing the indicators for all of the services returned for the given query, services can be compared and the best of them can be identified.

- DSP repository, which is the internal persistent data storage fed by the data collector and responsible for storing all data relevant to service profiles. Only the data collector can change information in the DSP repository. Other subsystems have read-only access to the repository.
- Event Manager, which handles workflow events. The event manager is the subcomponent responsible for processing workflow events and receiving execution logs. If any crucial information is included in such an event, it is passed to the data collector for further analysis.

As verified in the prototype implementation within the ASG project, such an architecture fulfils goals and requirements of a service profiling system.

SUMMARY

This chapter familiarizes users with the idea of Web services profiling. As a background, the current initiatives in the field of Web services description, especially non-functional properties and methods to derive the values of these properties, were presented. Moreover, the readers were introduced to different approaches to the quality-of-service concept. The focus of the chapter was placed on Web service profiling successfully implemented within the ASG system. A service profile, in its final state, aggregates all measured values of quality parameters to give a user the holistic view on a service quality. Taking into account information from profiles, it is possible to select the most suitable service, with regard to the user-specific quality expectations.

Chapter 7.14
On the Use of Web Services in Content Adaptation

Khalil El-Khatib

Gregor V. Bochmann
University of Ottawa, Canada

Abdulmotaleb El Saddik
University of Ottawa, Canada

ABSTRACT

The tremendous growth of the Internet has introduced a number of interoperability problems for distributed multimedia applications. These problems are related to the heterogeneity of client devices, network connectivity, content formats, and user's preferences. The challenge is even bigger for multimedia content providers who are faced with the dilemma of finding the combination of different variants of a content to create, store, and send to their subscribers that maximize their satisfaction and hence entice them to come back. In this chapter, the authors will present a framework for trans-coding multimedia streams using an orchestration of Web-services. The framework takes into consideration the profile of communicating devices, network connectivity, exchanged content formats, context description, users' preferences, and available adaptation services to find a chain of adaptation services that should be applied to the content to make it more satisfactory to clients. The framework was implemented as a core component for an architecture that supports personal and service mobility.

DOI: 10.4018/978-1-60566-330-2.ch008

INTRODUCTION

The tremendous growth of the Internet has introduced a number of interoperability problems for distributed multimedia applications. These problems are related to the heterogeneity of client devices, network connectivity, content formats, and user's preferences. The diversity of client devices, network connectivity, content formats, and user's preferences posed also some challenges in aligning and customizing the exchanged data between different users with different preferences. The challenge is even bigger for multimedia content providers who are faced with the dilemma of finding the combination of different variants of a content to create, store, and send to their subscribers that maximize their satisfaction and hence entice them to come back. Most content providers have taken the costly approach of creating different versions of content for different access devices and networks.

Content adaptation is an effective and attractive solution to the problem of mismatch in content format, device capability, network access and user's preferences. Using content adaptation, a number of adaptations is applied to the original content to make it satisfy the device constrains of the receiving device and the preferences of its user. Most currently available content adaptation modules are designed to make the Web easier to use. Examples of such adaptations modules include conversion of HTML pages to Wireless Markup Language (WML, 2001) pages, enlarging text size, reducing the size of an image, changing text and background colors for better contrast, removal of redundant information, audio to text conversion, video to key frame or video to text conversion, content extraction to list a few. These adaptation modules do not have though the same requirements and challenges of real-time multimedia content adaptations. Real-time multimedia applications involve large volumes of data making trans-coding a computationally very expensive task (Chandra & Ellis, 1999, Han et al.,1998). To address this challenge, some trans-coding services have been implemented in hardware and deployed on intermediate network nodes or proxies. The disadvantage of this approach is that there are always new types of clients that cannot be supported by the deployed hardware. A more suitable approach to address the computational challenge of multimedia trans-coding is based on the observation that the general trans-coding process can be defined as a combinatorial process (Mohan, Smith, & Li, 1999), and that multiple trans-coding services can be chained effectively together to perform a complex trans-coding task. So, instead of having all trans-coding done by one single trans-coding service, a number of trans-coding services can collaborate to achieve a composite adaptation task. For instance, trans-coding a 256-color depth *jpeg* image to a 2-color depth *gif* image can be carried out in two stages: the first stage covers converting 256-color to 2-color depth, and the second stage converts *jpeg* format to *gif* format. Using the software approach, transcoders can then be built more easily in software, and deployed and advertised more quickly to meet the needs of the users. Software-based trans-coding are also more reliable since its components can be simpler and they can also be replicated across the network. Moreover, transcoders can be modularized and re-used in different situations and contexts.

Given a composite adaptation task that can be carried out in a number of stages, and given that there could be a number of possible configurations to adapt the sender's content to make it presentable at the receiver's device, the challenge is to find the appropriate chain of available trans-coding services that best fits the capabilities of the device, and at the same time, maximizes the user's satisfaction with the final delivered content. In this chapter, we will discuss a Quality of Service (QoS) selection algorithm for providing personalized content through web-service composition. The function of the algorithm is to find the most appropriate chain of available trans-coding services between the sender and the receiver, and also to select the values for the configuration parameters for each trans-coding service. The proposed algorithm uses the user's satisfaction with the quality of the trans-coded content as the optimization metric for the path selection algorithm.

The rest of the chapter is organized as follows: In Section 2, we will introduce content adaptation and present the existing different models used in content adaptation. Section 3 lists all the required elements for providing customized content adaptation. In Section 4 we present our methodology for using the required element from Section 3 to construct a graph of trans-coding services; the algorithm for selecting the chain of trans-coding services is then presented. The selection criterion for the algorithm as well as its characteristics is also presented in Section 4, and finally, we end Section 4 with an example that shows step-by-step the results of the algorithm. Our conclusion is presented in Section 5.

CONTENT ADAPTATION

In today's Internet, there is a wide range of client devices in terms of both hardware and software capabilities. Device capabilities vary in different dimensions, including processing power, storage space, display resolution and color depth, media type handling, and much more. This variety on device capabilities makes it extremely difficult for the content providers to produce a content that is acceptable and appreciated by all the client devices (Fox, Gribble, & Chawathe, 1998), making application-level adaptation a necessity to cover the wide variety of clients.

There are three main approaches for handling this diversity in content formats: a static content adaptation, a dynamic content adaptation, and a hybrid of the static and dynamic approaches (Chang & Chen, 2002, Lum & Lau, 2002). The first two approaches differ in the time when the different content variants are created (Lei & Georganas, 2001) to match the requested format. In static adaptation, the content creator generates and stores different variants of the same content on a content server, with each variant formatted for a certain device or class of devices. Hafid and Bochmann (1996) presented an architecture for news-on-demand using this scheme. Static adaptation has three main advantages: (1) it is highly customized to specific classes of client devices, and (2) it does not require any runtime processing, so no delay is incurred, and (3) the content creator has the full control on how the content is formatted and delivered to the client. On the other hand, static adaptation has a number of disadvantages, mainly related to the management and maintenance of different variants of the same content (Lum & Lau, 2002): (1) different content formats need to be created for each sort of device or class of devices, and needs to be re-done when new devices are introduced, and (2) it requires large storage space to keep all variants of the same content.

With dynamic content adaptation, the content is trans-coded from one format to the other only when it is requested. Depending on the location where the trans-coding takes place, dynamic content adaptation technologies can be classified into three categories: server-based, client-based, and proxy-based. In the server-based approach (Mohan, Smith, & Li, 1999), the content server is responsible for performing the trans-coding; the content provider has all the control on how the content is trans-coded and presented to the user. Additionally, it allows the content to be trans-coded before it is encrypted, making it secure against malicious attacks. On the other hand, server-based adaptation does not scale properly for a large number of users and requires high-end content and delivery server to handle all requests.

As for the client-based approach (Björk et a., 1999, Fisher et al., 1997), the client does the trans-coding when it receives the content. The advantage of this approach is that the content can be adapted to match exactly to the characteristics of the client. But at the same time, client-based adaptation can be highly expensive in terms of bandwidth and computation power, especially for small devices with small computational power and slow network connectivity, with large volume of data might be wastefully delivered to the device to be dropped during trans-coding.

The third adaptation approach is the proxy-based approach (Chandra & Ellis, 1999, Chandra, Ellis, & Vahdat, 2000, Floyd & Housel, 1998, Fox, A., Gribble, Chawathe, Brewer, & Gauthier, 1997), where an intermediary computational entity can carry out content adaptation on the fly, on behalf of the server or client. Proxy adaptation has a number of benefits including leveraging the installed infrastructure and scaling properly with the number of clients. It also provides a clear separation between content creation and content adaptation. On the other hand, some content provider may argue that they prefer to have full control on how their content is presented to the user. Also, using proxies for adaptation does not allow the use of end-to-end security solutions.

CHARACTERIZATION AND REQUIREMENTS FOR CONTENT ADAPTATION

Advances in computing technology have led to a wide variety of computing devices, which made interoperability very difficult. Added to this problem is the diversity of user preferences when it comes to multimedia communications. This diversity in devices and user preferences has made content personalization an important requirement in order to achieve results that satisfy the user. The flexibility of any system to provide content personalization depends mainly on the amount of information available on a number of aspects involved in the delivery of the content to the user. The more information about these aspects is made available to the system, the more the content can be delivered in a format that is highly satisfactory to the user. These relevant aspects are: user preferences, media content profile, network profile, context profile, device profile, and the profile of intermediaries (or proxies) along the path of data delivery. We will briefly describe here each of these aspects; interested readers might refer to (El-Khatib & Bochmann, 2003) for more details.

User Profile: The user's profile captures the personal properties and preferences of the user, such as the preferred audio and video receiving/sending qualities (frame rate, resolution, audio quality…). Other preferences can also be related to the quality of each media types for communication with a particular person or group of persons. For instance, a customer service representative should be able to specify in his profile his/her preference to use high-resolution video and CD audio quality when talking to a client, and to use telephony quality audio and low-resolution video when communicating with a colleague at work. The user's profile may also hold the user's policies for application adaptations, such as the preference of the user to drop the audio quality of a sport-clip before degrading the video quality when resources are limited. The MPEG-21 standard (MPEG-21, 2001) is the most notable standards on user profiles.

Content Profile: Multimedia content might enclose different media types, such as audio, video, text, and each type can have different formats (Lei & Georganas, 2001). Each type has its format characteristics and parameters that can be used to describe the media. Such information about the content may include storage features, variants, author and production, usage, and many other metadata. The MPEG-7 standard (MPEG-7, 2000), formally named "Multimedia Content Description Interface", offers a comprehensive set of standardized description tools to describe multimedia content.

Context Profile: A context profile would include any dynamic information that is part of the context or current status of the user. Context information may include physical (e.g. location, weather, temperature), social (e.g. sitting for dinner), or organizational information (e.g. acting senior manager). The MPEG-21 standard includes tools for describing the natural environment characteristics of the user, including location and time, as well as the audio and illumination characteristics of the user's environment. Resource adaptation engines can use these elements to deliver the best experience to the user.

Device Profile: To ensure that a requested content can be properly rendered on the user's device, it is essential to include the capabilities and characteristics of the device into the content adaptation process. Information about the rendering device may include the hardware characteristics of the device, such as the device type, processor speed, processor load, screen resolution, color depth, available memory, number of speakers, the display size, and the input and output capabilities. The software characteristics such as the operating system (vendor and version), audio and video codecs supported by the device should also be included in the device profile. The User Agent Profile (UAProf) created by the Wireless Application Forum (WAP) and the MPEG-21 standard, both include description tools for describing device capabilities.

Network Profile: Streaming multimedia content over a network poses a number of technical challenges due to the strict QoS requirements of multimedia contents, such as low delay, low jitter, and high throughput (Ng, Tan, & Cheng, 2001). Failing to meet these requirements may lead to a bad experience of the user (Katchabaw, Lutfiyya, & Bauer,, 1998, Poellabauer, Abbasi, & Schwan, 2002). With a large variety of transport networks, it is necessary to include the network characteristics into content personalization and to dynamically adapt the multimedia content to the fluctuating network resources (Wu, Hou, Zhang, 2001). Achieving this requires collecting information about the available resources in the network, such as the maximum delay, error rate, and available throughput on every link over the content delivery path. A description tool for network capabilities, including utilization, delay and error characteristics are included in the MPEG 21 standard.

Profile of Intermediaries: When the content is delivered to the user across the network, it usually travels over a number of intermediaries. These intermediaries have been traditionally used to apply some added-value services, including on-the-fly content adaptations services (Chandra, Ellis, & Vahdat, 2000, Fox, Gribble, Chawathe, Brewer, & Gauthier, 1997). For the purpose of content adaptation, the profile of an intermediary would usually include a description of all the adaptation services that an intermediary can provide. These services can be described using any service description language such as the JINI network technology (JINI, 1998), the Service Location Protocol (Guttman, Perkins, Veizades, & Day, 1999), or the Web Service Description Language (WSDL, 2002). A description of an adaptation service would include, for instance, the possible input and output format to the service, the required processing and computation power of the service, and maybe the cost for using the service. The intermediary profile would also include information about the available resources at the intermediary (such as CPU cycles, memory) to carry out the services.

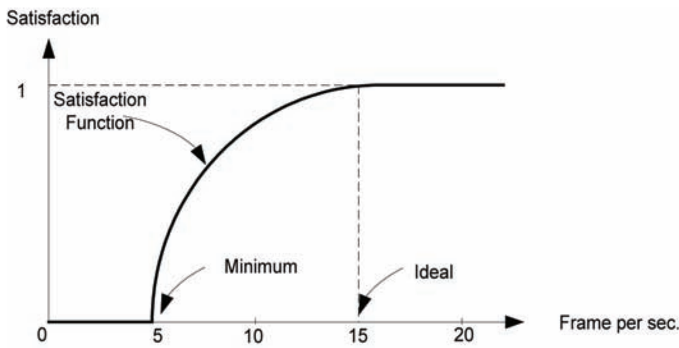
QOS SELECTION ALGORITHM

In this section, we will describe the overall QoS selection algorithm that finds the most appropriate chain of trans-coding services between the sender and the receiver, and also selects the configuration for each trans-coding service. We will first start by defining the user's satisfaction as the selection criterion for the algorithm, and then show how to construct the directed graph for adaptation, using the sender's content profile, receiver's device profile, and the list of available trans-coding services. After constructing the graph, we will show how to apply some optimization techniques on the graph to remove the extra edges in the graph, and finally present the actual QoS path and parameter selection algorithm.

User's Satisfaction as Selection Criteria

Most Internet users are indifferent about the underlying technologies such as protocols, codecs,

Figure 1. Possible satisfaction function for the frame rate.



or resource reservation mechanisms that enable their communication session. They are also indifferent about network level QoS characteristics, such as bandwidth, delay, or throughput. All what is important for these users in the end is making the communication session work in a satisfactory way: for instance, hearing without jitter and seeing without irregularity.

As we mentioned earlier, the user's preferences expressed in the user's profile can be classified as application layer QoS parameters. In order to compute the user's satisfaction with all values of the application layer configuration parameters, we have used the approach presented by Richards, Rogers, Witana, & Antoniades (1998), where each application level QoS parameter is represented by a variable x_i over the set of all possible values for that QoS parameter. The satisfaction or appreciation of a user with each quality value is expressed as a satisfaction function $S_i(x_i)$. All satisfaction functions have a range of [0..1], which corresponds to the minimum acceptable (M) and ideal (I) value of x_i. The satisfaction function $S_i(x_i)$ can take any shape, with the condition that it must increase monotonically over the domain. Figure 1 shows a possible satisfaction function for the frame rate variable.

In the case when there are more than one application parameter (frame rate, resolution, color depth, audio quality,…), Richards *et. al.* proposed using a combination function f_{comb} that computes the total satisfaction S_{tot} from the satisfactions s_i for the individual parameters (Equa. 1).

$$S_{tot} = f_{comb}(s_1, s_2, s_3 \ldots, s_n) = \frac{n}{\sum_{i=1}^{n} \frac{1}{s_i}} \tag{1}$$

Extending User's Satisfaction to Support Weighted Combination and Multi-User Conference Sessions

We think that the approach described above is a major step towards a simple user-friendly interface for user level QoS specification, however, further considerations could be taken into account as described below. A first improvement results from the observation that users in telecommunication session might find some media types more important than others. For instance, a user of a news-on-demand service might prefer to receive high quality audio with low quality video as compared to average quality audio and average quality video. In the case of a user watching a sport event the situation may be the opposite (if the user does not care about the audio of the commenter).

This preference to individual media can play a factor when it comes to the calculation of the total satisfaction S_{tot}. By assigning different weights w_i to the different parameters x_i, S_{tot} will reflect the user preference for different media types. The combination function for the total user satisfaction can be redefined as follows:

$$S_{tot}^{user} = f_{comb}(s_1, s_2, s_3 \ldots, s_n, w_1, w_2, w_3 \ldots, w_n) = \frac{n\bar{w}}{\sum_{i=1}^{n} \frac{w_i}{s_i}} \tag{2}$$

where w_i is the weight for the individual satisfaction s_i and $\bar{w} = \frac{\sum_{i=1}^{n} w_i}{n}$. Equa. 2 have similar properties as Equa. 1, which is to:

Prop. 1. One individual low satisfaction is enough to bring the total satisfaction to a low value.

Prop. 2. The total satisfaction of equal individual satisfactions s_i with equal weight is equal to the satisfactions s_i.

These constants weight factors (AudioWeightFactor, VideoWeightFactor,..) can be selected by the user, and stored in the user profile. The selection of these weights depends on the type of service the user is willing to receive when using a specific service or communicating with a given callee.

Additionally, we have so far considered only the QoS preferences of a single user. But all conversational multimedia applications involve several users. It is therefore important to determine how the possibly conflicting preferences of the different users are reconciled in order to come up with QoS parameters that are suitable for all participating users.

In certain circumstances, some given parameters may be determined simply based on the preferences of a single user. This may be the case in a two-way teleconference between two users A and B, where the parameters of the video visible by User A would be determined based on the preferences of User A alone, and the video in the opposite direction based on the preferences of User B. However, the situation may be more complex if the cost of the communication is paid by User A and the selection of the video received by User B has an impact on the communication cost.

In other circumstances, as for instance in the case of the joint viewing of a video clip by several participants in a teleconference, the selected quality parameters should be determined based on the preferences of all participating users. In such circumstances, we propose to use the same combination function for user satisfaction considered above and (optionally) introduce a weight for each of the participating users, called the *QoS selection weight*, which determines how much the preferences of the user influences overall QoS parameter selection. The total satisfaction (computed for all users) is then given by

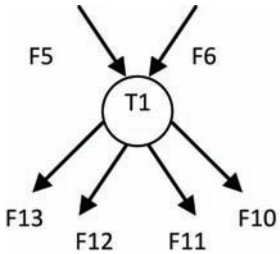
$$S_{tot} = f_{comb}(s_{tot}^{usr_1}, s_{tot}^{usr_2} \ldots, s_{tot}^{usr_m}, a_1, a_2 \ldots, a_m) = \frac{m\bar{a}}{\sum_{i=1}^{m} \frac{a_i}{s_{tot}^{usr_i}}} \tag{3}$$

where $s_{tot}^{usr_i}$ is the total satisfaction for user *i*, and a_i is the *QoS selection weight* for user *i*. In the case that the weight of a given user is zero, the preferences of this user are not taken into account for the selection of the QoS parameters.

Constructing a Directed Graph of Trans-Coding Services

Now that we have decided on the selection criteria, the first step of the QoS selection algorithm would be to construct a directed acyclic graph for adaptation, using the content profile, device profile, and the list of available trans-coding services. Using this graph, the route selection algorithm would then determine the best path through the graph, from the sender to the receiver, which maximizes the user's satisfaction with the final received adapted

Figure 2. Trans-coding service with multiple input and output links



content. The elements of the directed graph are the following:

1. Vertices in the graph represent trans-coding services. Each vertex of the graph has a number of properties, including the computation and memory requirements of the corresponding trans-coding service. Each vertex has a number of input and output links. The input links to the vertex represent the possible input formats to the trans-coding service. The output links are the output formats of the trans-coding service. Figure 2 shows a trans-coding service T1, with two input formats, F5 and F6, and four possible output formats, F10, F11, F12 and F13. The sender node is a special case vertex, with only output links, while the receiver node is another special vertex with only input links.

   To find the input and output links of each vertex, we rely on the information in different profiles. The output links of the sender are defined in the content profile, which includes as we mentioned earlier, meta-data information (including type and format) of all the possible variants of the content. Each output link of the sender vertex corresponds to one variant with a certain format. The input links of the receiver are exactly the possible decoders available at the receiver's device. This information is available through the description of the receiver's device in the device profile. The input and output links of intermediate vertices are described in the service description part of the intermediaries profile. Each intermediary profile includes the list of available trans-coding services, each with the list of possible input and output formats. Each possible input format is represented as an input link into the vertex, and the output format is represented as an output link.
2. Edges in the graph represent the network connecting two vertices, where the input link of one vertex matches the output link of another vertex.

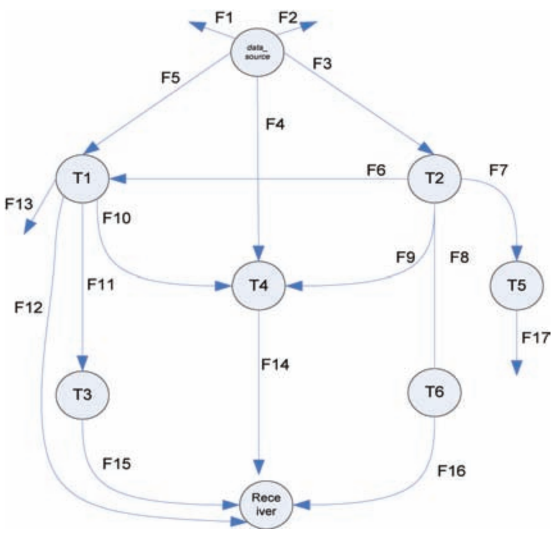
   To construct the adaptation graph, we start with the sender node, and then connect the outgoing edges of the sender with all the input edges of all other vertices that have the same format. The same process is repeated for all vertices. To make sure that the graph is acyclic, the algorithm continuously verifies that all the formats along any path are distinct.

   Figure 3 shows an example of an adaptation graph, constructed with one sender, one receiver, and seven intermediate vertices, each representing a trans-coding service. As we can see from the graph, the sender node is connected to the trans-coding service T1 along the edge labeled F5. This means that the sender S can deliver the content in format F5, and trans-coding service T1 can convert this format into format F10, F11, F12, or F13.

Adding Constraints to the Graph

As we have discussed earlier, the optimization criterion we have selected for the QoS selection algorithm is the user's satisfaction computed using the function f_{comb} presented in Section 4.2. The maximum satisfaction achieved by using a trans-coding service T_i depends actually on a number of factors.

Figure 3. Directed trans-coding graph



The first factor is the bandwidth available for the data generated by the trans-coding service T_i. The more bandwidth is available to the trans-coding service, the more likely the trans-coding service will be able to generate trans-coded content that is more appreciated by the receiver. The available bandwidth between two trans-coding services is restricted by the amount of bandwidth available between the intermediate servers where the trans-coding service T_i is running and the intermediate server where the next trans-coding service or receiver is running. We can assume that connected trans-coding services that run on the same intermediate server have an unlimited amount of bandwidth between them.

Other factors that can affect the user's satisfaction are the required amount of memory and computing power to carry out the trans-coding operation. Each of these two factors is a function of the amount of input data to the trans-coding service.

Graph Optimization

By looking at the graph in Figure 3, we can see that there are some edges like F1, F2 or F17 that are connected only to one trans-coder. These edges cannot be a part of any path from the sender to the receiver. The same principle also applies to trans-coders other than the sender and receiver that are not on any path from the sender to the receiver. T5 is an example of a trans-coder that cannot be used to send data through it on the way from the sender to the receiver. Removing these edges and vertices help reduce the computational time of the algorithm, since it helps pruning dead-ends from the graph. Applying optimization for the graph in Figure 3 would result in the graph shown in Figure 5. The pseudo-code for the graph optimization is shows in Figure 4.

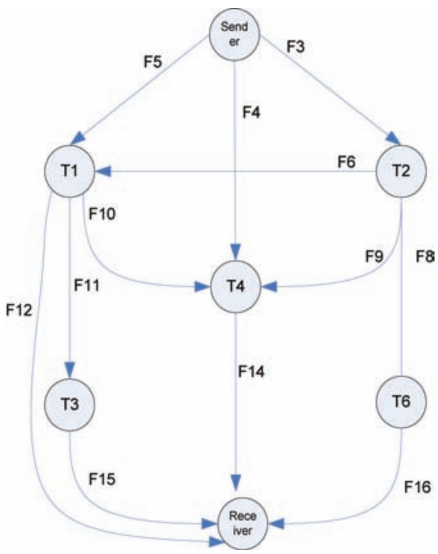
QoS Selection Algorithm

Once the directed acyclic adaptation graph has been constructed, the next step is to perform the

Figure 4. Pseudo-code for the graph optimization

```
graph_optimization(Transcoder t){
    if t ≠ receiver then {
            for all ne ≠ neighbor(t)
                    graph_optimization(ne);
            if is_empty(neighbor(ne)) then
                    delete(ne);
                    }
}
```

Figure 5. Optimized directed trans-coding graph



QoS selection algorithm to find a chain of trans-coding services, starting from the sender node and ending with the receiver node, which generates the maximum satisfaction of the receiver. Finding such as path can be similar to the problem of finding the shortest path in a directed weighted graph with similar complexity, except that the optimization criterion is the user's satisfaction, and not the available bandwidth or the number of hops.

Our proposed algorithm uses two variables representing two sets of trans-coding services, the set of already considered trans-coding services, called VT, and the set of candidate trans-coding services, called CS, which can be added next on the partially selected path. The candidate trans-coding services set contains the trans-coding services that have input edges coming from any trans-coding service in the set VT. At the beginning of the algorithm, the set VT contains only the *sender* node, and CS contains all the other trans-coding services in the graph that are connected to *sender*, and also the *receiver*. In each iteration, the algorithm selects the trans-coding service T_i that, when using it, generates the highest user satisfaction. The user satisfaction is computed as an optimization function of the audio and video parameters for the output format for T_i, subject to the constraint of available bandwidth between T_i and its ancestor trans-coding service, and also subject to the remaining user's budget. T_i is then added to VT. The CS set is then updated with all the neighbor trans-coding services of T_i. The algorithm stops when the CS set is empty, or when the *Receiver* node is selected to be added to VT. The complete description of the algorithm is given in Figure 6.

As indicated in Step 2 and Step 8, the algorithm selects from CS the transcoder T_i that can generate the highest satisfaction value for the receiver. To compute the satisfaction value for each transcoder T_i in CS, the algorithm selects the QoS parameter values x_i that optimize the satisfaction function in Equa. 2, subject only to the constraint remaining user's budget and the bandwidth availability that connects T_i to T_{prev} in VT. i.e.

$$bandwith\_requirement(x_1..x_n) \leq Bandwidth\_AvailableBetween(T_i, T_{prev}). \qquad (4)$$

Since each trans-coding service can only reduce the quality of the content, when the algorithm terminates, the algorithm would have computed the best path of trans-coding services from the *sender* to the *receiver*, and the user's satisfaction value computed on the last edge to the receiver node is the maximum value the user can achieve. To show this, assume that the selected path is the path $\{T_{11}, \ldots T_{1n}\}$ in Figure 7. If the path $\{T_{21}, \ldots T_{2m}\}$ is a better path, then T_{2m} should have converted the content into variant that is more appreciated by the user than the variant generated by T_{1n}. Since transcoders can only reduce the quality of content, all transcoders along the path $\{T_{21}, \ldots T_{2m}\}$, should have also produced a content with higher satisfaction function than the variant produce by T_{1n}, and hence all these transcoders should have been selected before T_{1n}, which contradicts with the assumption.

Figure 6. QoS selection algorithm

```
Step 1: // Let VT be the set of all considered trans-coding services.
        VT = {sender};
// Let CS be the set of all direct neighbor transcoders of all transcoders in VT
     CS = neighbor(sender);
        // Let user_budget be the amount of money the user is willing to pay
Step 2: // Each trans-coding service keeps a track of its parent trans-coding service. Let T_prev be the trans-coding services in CS connected to
        // T_i; Compute the perceived user's satisfaction for using all the trans-coding services in CS, subject to two constraints: the remaining
        // user budget and the available bandwidth between T_i and T_prev.
        For □ T_i □ CS
          Optimize( user_profile, input_format, output_format, Sat_T[i],
                              user_budget,cost,available_bandwith)
Step 3: // If there are no more transcoders to consider and the receivers can
        // not be reached from the sender through any transcoding path.
        if is_empty(CS) then
           TERMINATE(FAILURE)
Step 4: Select the trans-coding service T_i that has the highest satisfaction
        value Sat_T[i], for the user.
        CS = CS – { T_i };
Step 5: VT = VT + { T_i };
Step 6: Let T_i. previous_selected_transcoder = T_prev;
        T_i.accumulated_cost = T_i.previous.accumulated_cost + transcoding_and_transmission_cost [i];
Step 7: if T_i = receiver , then GOTO Step 10
Step 8: // compute the satisfaction for using all the neighboring transcoders of T_i and add them to CS
        For □ T_j □ neighbors( T_i );
          Optimize( user_profile, input_format, output_format, Sat_T[i], user_budget,cost[i],available_bandiwth)
           CS = CS □ {T_j };
Step 9: GOTO Step 3
Step 10:   Print the reverse path from the Receiver to the Sender by following the link "previous" of all transcoders, starting from the Receiver.
```

Figure 7. Graph selection

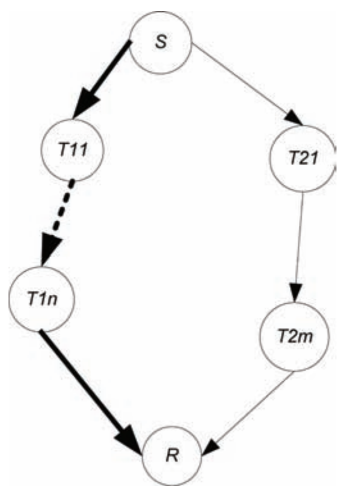


Figure 8. Example of trans-coding graph

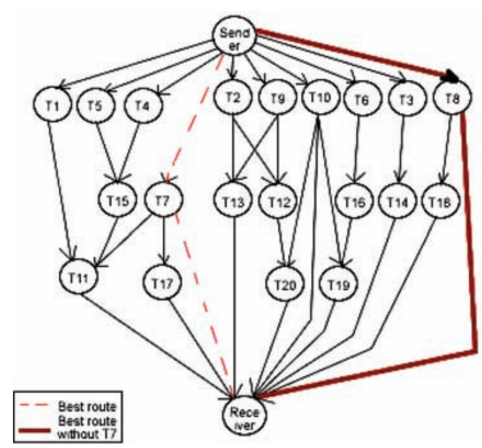

Example

In this section, we will present an example to show how the QoS path selection algorithm works. We will assume that the graph construction algorithm has generated the graph shown in Figure 8. The graph also shows the selected path with and without trans-coding service T_7 as part of the graph. The selected trans-coding services, user satisfaction, as well as the best current path produced by the algorithm are also shown in Table 1. Each row in the table shows the results for one iteration of the algorithm.

Table 1. Results for each step of the path selection algorithm

Round	Considered Set (VT)	Candidate set (CS)	Selected transcoding service	Selected Path	Delivered Frame Rate	User satisfaction
1	{ *sender* }	{T1, T2, T3, T4, T5, T6, T7, T8, T9, T10}	T10	*sender*,T10	30	1.00
2	{ *sender*, T10}	{T1, T2, T3, T4, T5, T6, T7, T8, T9, T19, T20, *receiver*}	T20	*sender*, T10, T20	30	1.00
3	{ *sender*, T10, T20}	{T1, T2, T3, T4, T5, T6, T7, T8, T9, T19, *receiver*}	T5	*sender*,T5	27	0.90
4	{ sender, T10, T20, T5}	{T1, T2, T3, T4, T6, T7, T8, T9, T19, T15, receiver}	T4	sender,T4	27	0.90
5	{ sender, T10, T20, T5, T4}	{T1, T2, T3, T6, T7, T8, T9, T19, T15, receiver}	T3	sender,T3	23	0.76
6	{ sender, T10, T20, T5, T4, T3}	{T1, T2, T6, T7, T8, T9, T19, T15, T14, receiver}	T2	sender,T2	23	0.76
7	{ sender, T10, T20, T5, T4, T3, T2}	{T1, T6, T7, T8, T9, T19, T15, T14, T12, T13, receiver}	T1	sender,T1	23	0.76
8	{ sender, T10, T20, T5, T4, T3, T2, T1}	{T6, T7, T8, T9, T19, T15, T14, T12, T13, T11, receiver}	T11	sender,T1, T11	23	0.76
9	{ sender, T10, T20, T5, T4, T3, T2, T1, T11}	{T6, T7, T8, T9, T19, T15, T14, T12, T13, receiver}	T13	sender,T2, T13	23	0.76
10	{ sender, T10, T20, T5, T4, T3, T2, T1, T11, T13}	{T6, T7, T8, T9, T19, T15, T14, T12, receiver}	T12	sender,T2, T12	23	0.76
11	{ sender, T10, T20, T5, T4, T3, T2, T1, T11, T13, T12}	{T6, T7, T8, T9, T19, T15, T14, receiver}	T14	sender,T3, T14	23	0.76
12	{ sender, T10, T20, T5, T4, T3, T2, T1, T11, T13, T12, T14}	{T6, T7, T8, T9, T19, T15, receiver}	T8	sender, T8	20	0.66
13	{ sender, T10, T20, T5, T4, T3, T2, T1, T11, T13, T12, T14, T8}	{T6, T7, T9, T19, T15, receiver}	T7	sender, T7	20	0.66
14	{ sender, T10, T20, T5, T4, T3, T2, T1, T11, T13, T12, T14, T8, T7}	{T6, T9, T19, T15, receiver}	T6	sender, T6	20	0.66
15	{ sender, T10, T20, T5, T4, T3, T2, T1, T11, T13, T12, T14, T8, T7, T6}	{T9, T19, T15, receiver}	receiver	sender, T7, receiver	20	0.66

FUTURE RESEARCH DIRECTION

In this section, we will outline some potential directions for future research works.

In this chapter, we have not addressed the issues regarding autonomic service management of real-time multimedia services. One of the challenges is the efficient, autonomous management of these real-time content adaptation services in future generation networks. The autonomous service management is crucial for the self-management of real-time multimedia services. According to Ganek and Corbi of IBM (Ganek and Corbi, 2003), the autonomous or self-management aspects include self-optimizing, self-healing, self-configuring, and self-protecting. The existing approach and framework contributes towards a system that is not fully autonomic in all four management aspects.

Current, we are looking at nature-inspired automatic service management solution that is inspired from the Bee colony metaphor. The allegory comprises how bee agents mimic functional services related to multimedia applications, in order to autonomously monitor and configure multimedia services. The objective of this research is to ensure complete autonomic behaviour of the four main management activities (configuration, repair, optimization and protection) of an autonomous system. Such direction could enable customization of the service for the current and future generation network conditions.

CONCLUSION

Content adaptation is a natural solution to address the problem of heterogeneity of Internet clients and users. In this chapter, we have presented a solution to the problem of heterogeneity which takes into consideration the capabilities of the client devices, network connectivity, content format, and users' preferences. An important part of the framework is the QoS path selection algorithm that decides on the chain of adaptation services to add and the configuration parameters for each service. The decision is based on the profile of communicating devices, network connectivity, exchanged content formats, context description, and available adaptation services.

Chapter 7.15

Reconceptualising Information Literacy for the Web 2.0 Environment?

Sharon Markless
King's College, London, UK

David Streatfield
Information Management Associates, UK

ABSTRACT

This chapter questions whether the shift from the Web as a vehicle for storing and transmitting information to the new Web as a series of social networking environments, requires significant changes in how students interact with information when they are studying within a formal learning environment. It explores the origins and growth of the idea of information skills development, the translation of this work into frameworks and sequential models and the adaptation of these models to take account of changes in information storage and transmission brought about by the Internet. The chapter then examines the changing contexts and changes in learning being brought about by the Web 2.0 environment and questions whether adjustment of existing information literacy models is a sufficient response to deal with these changes. We conclude that although Web 2.0 developments are not fundamentally undermining the nature of teaching and learning they do provide important possibilities for more effective information literacy development work. A non-sequential framework is offered as a contribution to supporting HE students when seeking to obtain, store and exploit information simultaneously in the informal social world of Web 2.0 and in their formal academic discipline.

THE RISE OF INFORMATION SKILLS

In the early 1980s a spate of books appeared in the UK containing a new term in the title: 'information skills'. This term was the brainchild of a working party concerned about school pupils' competence in *"using libraries, exploring references and making notes"* (Marland, 1981, p7) and arose out of the Schools Council's desire to explore what a curriculum for a changing world might comprise. The working party report asserted that *"Individuals today have an increasing need to be able to find things out…never before have our lives depended so much on our ability to handle information successfully"* (Marland, 1981, p9). Narrow concerns about library skills and user education were replaced by a focus on students' problems in finding and using information to tackle assignments and conduct their research within a formal learning environment. This intervention was due to the interest in these skills by educationalists, who, working alongside librarians, ensured wider adoption for information skills and a clearer place for the concept within the learning process.

However, despite this development and the appearance of a number of books exploring the place of information skills in learning (see, for example, Markless and Lincoln, 1986, and Wray, 1985) the concept of information skills was far more widely accepted by librarians than by teachers. This resulted in heavy emphasis on competence in resource use and on finding information.

MODELS OF INFORMATION SKILLS

From the outset writers wanted to show the need for students to develop these 'new' information skills. The issue was presented as one of skills deficit and consequently led to a plethora of information skills frameworks and models, spelling out what students should be able to do. (Many of these models were later 'rounded up' and described by Loertscher and Woolls, 2002.) Model constructors conceived the requisite process as tying together distinct elements of information-related behaviour into a logical, sequential process which could then be taught (e.g. Marland, 1981; Brake, in Markless and Lincoln 1986).

An important retrospective review of these models and frameworks (Eisenberg and Brown, 1992) concluded that

while each author may explain this process with different terms … all seem to agree on the overall scope and the general breakdown of the process … it appears that the various process models are more alike than different and it may be possible and desirable to begin speaking about a common process approach to library and information skills instruction. (p. 7)

The approach to information skills as a 'common process' to be applied to library research and information handling unfortunately tended to result in a disregard for the context of learning. Skills were perceived as generic; the sequential process outlined in the models was to be adopted at all ages and across different subjects. The process formed a 'curriculum' to be taught to students and applied by them whenever necessary. This view was hardly challenged in the early world of information skills although research on information behaviour in context and on critical thinking skills was calling into question the whole notion of easy transfer, which is also a well-established assumption in mainstream education (Perkins and Salomon, 1992).

Perhaps the most influential of these generic information skills models was advanced as the Big6. This model was created by Eisenberg and Berkowitz (1990); it was widely disseminated in book form and continues to be heavily promoted in the USA and internationally through their website and through an extensive programme of workshops. We will use this Big6 framework as the basis of our critique for the remainder of this chapter because it is one of the frameworks most widely used in USA and UK schools to support information skills teaching and because its authors were amongst the first to integrate ICT into information skills in a distinct and transparent manner.

THE BIG SIX SKILLS™ APPROACH

The main elements of this model are outlined below:

1. Task Definition: (determine the purpose and need for information)
   - Define the problem
   - Define the information requirements of the problem
2. Information Seeking Strategies: (examining alternative approaches to acquiring the appropriate information to meet needs)
   - Determine the range of possible resources
   - Evaluate the different possible resources to determine priorities
3. Location and Access: (locating information sources and information within sources)
   - Locate sources (intellectually and physically)
   - Finding information within resources
4. Use of Information: (using a source to gain information)
   - Engage (e.g. read, hear, view) the information in a source
   - Extract information from a source
5. Synthesis: (integrating information drawn from a range of sources)
   - Organize information from multiple sources
   - Present information
6. Evaluation: (making judgements based on a set of criteria)
   - Judge the product (effectiveness)
   - Judge the information problem-solving process (efficiency)

   Eisenberg and Berkowitz (1990)

It is not surprising that when the concept of information skills was new, and people sought to understand its scope, frameworks such as the Big6 were widely adopted. They provided a foundation on which to build learning activities and assessment. Would such frameworks survive intact into the 'information age' of ICT?

THE SHIFT TO INFORMATION LITERACY: A BROADER VIEW?

With the advent of Worldwide Web and the extensive accompanying investment in ICT in educational institutions of all kinds, concerns about students' ability to find and use information grew exponentially and a new vocabulary began to emerge in formal education - that of information literacy. The notion of information literacy developed in the USA in the 1980s in response to a move towards more active learning in universities and the concomitant need to move away from terms implying passive instruction (Martin, 2006). Use of the term expanded considerably in the 1990s (Bawden, 2001) and has gained some worldwide influence, leading to a declaration by UNESCO (2003) stressing the global importance of information literacy within the information society. A parallel growth in the UK has seen the term widely adopted in academic libraries and national educational bodies (but with most school libraries until now still preferring to focus on information skills - Streatfield and Markless, 2007).

Did the new term signify any fundamental change in thinking or signal a new characterisation of the skills or processes previously called information skills? National Information Literacy Standards in Australia (CAUL, 2001) and the USA (ACRL, 2000) echoed much of what was in the earlier process models, as did the information literacy model proposed in the UK by the Society of College, National and University Libraries (1999). Despite the fact that 'literacy' is a problematic and contested concept (it has been variously described as encompassing notions of functional competence and skills, of sets of wider cognitive abilities, and as part of a contextualised approach to learning in its social and economic context - Bowden, 2001), information literacy was usually reduced in presentation to a series of skills, procedures and technicalities. This inhibited approach attracted some criticism for being too mechanistic and some writers moved towards a conceptualization that includes attitudes, underpinning knowledge and meta-cognitive abilities (Kuhlthau, 1988; Bruce, 1997). Although Kuhlthau recognised the importance of student attitudes and emotions in her information process model, these elements have not been integrated into other process models - although the commentaries accompanying these models usually refer in some way to motivation and attitudes.

INFORMATION SKILLS AND THE INTERNET

In this phase of its development, the Internet was viewed primarily as a new information storage and delivery system for which existing information skills frameworks could simply be expanded or adapted to take account of the growth in access to information via the Internet. Eisenberg and Johnson (1996) exemplified this view when they explicitly integrated ICT into the Big6 Skills model, saying that

Students need to be able to use computers flexibly, creatively and purposefully… (they) should be able to use the computer as part of the process of accomplishing their task. (p. 2)

During the 1990s, the creators of the Big6 confidently extended the model to include student use of ICT when solving learning problems. They claimed that various computer and information technology skills were integral parts of the Big6 Skills. This claim was sustained as their model continued to be implemented in schools across the USA and the UK (Eisenberg and Berkowitz, 2000). Adherents of this and other process models confidently asserted that the basic principles of information seeking and use, derived from years of watching and helping students to interact with print-based information, remained unchallenged.

We have chosen to exemplify current process models by citing the Big6 when looking at whether the concept of information literacy needs to be repackaged or reconceptualised because:

- the model crystallizes the general process approach favoured until now and serves as an adequate exemplar of the model-driven approach
- it serves our purpose because it was the only model advanced until recently that systematically encompasses the ICT dimension
- It is still currently being used and promoted in that form.

The Big6 framework is useful for this purpose because it is a systematic and widely adopted model. Our comments should not be construed as an attack on this particular framework.

EXAMINING THE PROCESS MODELS

What are the assumptions underpinning the Big6 and similar models and what are their main characteristics?

- A sequential view of the process of student research, conceived as a series of logical steps
- Use of prescriptive language to convey an 'ideal approach' to information-seeking and use (e.g. "After students determine their priorities for information-seeking they must locate information from a variety of sources"; "once the information problem has been formulated, the student must consider all possible information sources and develop a plan for searching").

This approach is commonplace in this period, despite the warning offered a decade earlier by Tabberer and Altman (1986) about the danger of idealising study behaviour and promoting 'the right way to …' They stressed that success came by diverse routes and as a result of different choices made in different situations. They warned that students did not always gain much by being confronted with 'the ideal' because there is a range of influences that prevent adoption of 'best behaviour'.

- The process models were designed to support information skills teaching (i.e. to provide a 'curriculum' for the teachers and a pathway to be followed by students when doing their research).
- A particular and limited conception of information-related behaviour is represented in these models, with much emphasis on information seeking, location and access. Use of information is reduced to determining relevance and extracting pertinent items of information (by taking notes or resorting to cut and paste). The words knowledge, understanding and making sense of, seldom occur in these models, nor does the idea of creating one's own viewpoint. The apparent assumptions are that this shortcoming will be addressed in the subject teaching or that the acts of extracting and organising relevant information will themselves stimulate the construction of meaning. What happens instead is frequently cut and paste activity leading to more or less unintentional plagiarism. In these models, synthesis is not about transforming information to encapsulate new knowledge
- Overall they present ways to support teaching ("innovative instructional methods") designed to provide a framework to guide teachers or librarians when preparing appropriate activities or tasks for their students.

These models reflected the main uses conceived for the Web in this period as a vehicle for storing and transmitting information.

INFORMATION LITERACY AND WEB 2.0: CHANGING THE CONTEXT, CHANGING THE LEARNING?

The 'orthodoxy' of information skills within formal learning environments, as enshrined in the Big6 Model, is being increasingly challenged. Recent research into information literacy is moving away from technological processes and skills-based models, recognising the complexities inherent in finding and using information. A more experiential perspective that recognises the contextual and affective elements of information literacy is emerging (Williams and Wavell, 2007). Two complementary developments have influenced this shift in focus: greater interest amongst information literacy researchers and practitioners in the processes of learning (especially theory about variation in learning and constructivist approaches); and an electronic environment that is increasingly being shaped by its users.

Have traditional views of information literacy really been rendered obsolete? Does learning through Web 2.0 require different skills and abilities? Are a new range of cognitive and metacognitive strategies needed to learn effectively within the Web 2.0 environment? Or, does the Web 2.0 environment provide tools that enable teachers to engage students more effectively in well-established learning processes than could be achieved hitherto?

In our view, learning is not fundamentally different within Web 2.0, nor does the 'new' social software change the basic processes of learning. Where Web 2.0 has made a difference is in making it easier to engage with some aspects of learning that were previously difficult to address (for example, real collaboration and groupwork, peer critique, hearing students' authentic voices and construction of new knowledge). None of these important aspects of effective learning are new: all can be found in the education literature of the 20th Century, from Dewey to Ausubel, and from Vygotsky to Marton. However, despite their importance, few of these elements have found their way into information literacy models or practice.

When the Worldwide Web was primarily a vehicle for storing and delivering information it was easy to portray information literacy as an ordered sequence of skills to be ***transmitted*** to students, whilst ignoring other approaches to learning. Web 2.0 effortlessly undermines this approach with its disregard for authority, hierarchy and order and its focus on the voice of the individual and on ever changing constructed groups. Any contemporary approach to information literacy must consider how to engage more effectively with learners, by understanding these multiple aspects of how they can learn.

Before we examine in a little more detail some of these key elements of learning and their relationship to information literacy and social software, we need to note two other factors that may influence this relationship: the reluctance of individuals and institutions to change; and the ways in which the 'Google generation' of 'digital natives' may interact with information and learn in new and different ways. What are the key elements of learning as they relate to information literacy and social software? Some at least of these key elements are:

1. Reluctance to change (institutions and teachers)

Faced with the unfamiliar challenge of a new world of social networking, some education institutions have tended to react in a predictably conservative way by blocking access to elements such as Face book and Second Life. As a result of such embargos, as well as a reluctance by teachers to engage with this new world, students are frequently operating in different electronic environments during formal learning from those in their out of hours experience (especially in schools). This makes teaching of information literacy more problematic.

To somewhat over-dramatize the dilemmas created: as a teacher, how can you fully engage with students in helping them to exploit information if you don't have easy access to what may constitute their major sources of information? Or, from a student perspective, why should you bother to engage with all this 'information literacy stuff' if your perception is that all you have to do to get the information and help that you need, is to resort to your social networks? When you are away from the institution, if you can effortlessly manipulate multi-media information to build your own web pages, why jump through what might be seen as sterile and irrelevant information literacy hoops when you are in formal learning mode? Again, as the world of Web 2.0 becomes increasingly sophisticated, the version of ICT encountered in formal learning is likely to appear ever more limited and pedestrian.

2. Digital natives and others

" Future students in higher education belong to a generation that has grown up with a PC mouse in their hands, a TV remote control, a mobile phone, an i-pod, a PDA and other electronic devices for communication and entertainment … computer games, the Internet, MSN, wikis and blogs being an integral part of their lives" (Veen, 2007, p.1). Prensky has labelled these young people 'digital natives' and has asserted that they now exhibit different characteristics from their forbears (the digital immigrants) due to the extent of their exposure to technology in all its forms.(Prensky, 2001). He claims that changes in activity during development may result in different neural wiring via processes of 'neuro-plasticity'; a view recently echoed by Martin Westwell of the Institute for the Future of the Mind (2007). Both advocates assert that current students have much better visual skills, do better at visual-spacial tests, are able to deal with lots of information at once, and can process this information and make decisions quickly. On the other hand, this generation of students may have shorter attention spans, be easily distracted, may not maintain focus well when interrupted and may have less ability to reflect on topics than the previous generation. Veen (2007) adds to this list of differences, talking about non-linear learning behaviour; clicking and zapping to deal with information overload; using exploratory approaches to new situations; and becoming experienced at problem solving at a young age. “We now have a new generation with a very different blend of cognitive skills than its predecessors – the digital natives.” (Prensky, 2001)

As a result of Web 2.0 developments, we can also anticipate that ‘digital natives’ may have different social skills.. This is because the Internet is increasingly used for socialisation rather than just information-seeking, with even those seeking information often doing so via peer groups. Westwell claims that more people use Second Life and Facebook than use Google. Whether or not we believe all these claims, Oblinger and Oblinger (2005) have forecast that the next generation of students entering higher education will be digitally literate, highly Internet-familiar, connected via networked media, used to immediate responses, and preferring experiential learning. This generation will be highly social: they will prefer to work in teams and will crave interactivity in image-rich environments as distinct from text-intensive environments.

Where does this leave traditional information literacy, with its focus on using libraries and finding primary sources, its reliance on laborious sequential steps and its scant reference to collaboration or to multi-media resources? If Westwood and others are correct, their picture of our ‘new’ students implies that not only have they gained from their early digital experiences but they have also lost in terms of opportunities for reflection and ‘slow-learning’. This picture of gains and losses calls into question the widespread claims that elements of Web 2.0 (wikis etc.) automatically help to develop meta-cognitive skills. However, it is also interesting to note that traditional information literacy frameworks do not emphasise reflection and its role throughout learning.

WEB 2.0, INFORMATION LITERACY AND FORMAL LEARNING

Where do all these changes leave information literacy? How might traditional models of information literacy need to be altered to accommodate the experience and expectations of students within formal education? Where does Web 2.0 fit in?

- The sequential view of skills deployment is now being questioned. Learning tasks make a range of different demands on students, which call into question the notion of applying the same series of steps to meet all these demands. Observations of pupils from 5-18 in schools and students in further education colleges show that they seldom follow the prescribed sequence (Streatfield and Markless, 1994; Moore, 1997; Markless and Streatfield, 2000). Formal studies of information-seeking behaviour in universities again challenge this premise (Foster, 2006). To be fair, most of the process models that are set out in steps are accompanied by some form of caveat recognising or even advising that it is not necessary to follow the prescribed sequence. However, there is usually little help offered on how to use the model in a non-sequential way, with the result that the framework tends to be taught as a sequence. The desire to inflict sequences on students is remarkably resilient in the world of information literacy. Even writers who are responding to the Web 2.0 environment tend to present a sequence of processes to be learned in order to become 'information fluent' (e.g. the five-stage process of Jukes (2007): asking questions; accessing data; analysing and authenticating information; applying it to real-life problems; assessing product and process). This approach takes no account of the influence of context on any sequence, the influence of learners' cognitive styles, or the need to make sense of any information and transform it into knowledge.

In addition, a core characteristic of Web 2.0 tools is that they transfer power, ownership and authority to the participants. This inevitably gives people license to design their own routes through learning tasks in any way that suits them. Finding information is less likely to involve systematic information seeking than, for example, interest groups, peer web pages or social bookmarking.

These observations lead to the key question - can the Big6 or any similar information literacy model be adapted to take account of how students actually find and use information, especially in the Web 2.0 environment?

- Although the importance of learning as construction is recognised within the rhetoric of information skills pedagogy and "Information literacy is often seen as the school library version of constructivism" (Moore, 2005 p.3), much of the observed planning and practice[1] suggests heavy reliance on transmission, learner practice, and feedback, all heavily structured into manageable segments and strongly 'teacher' controlled (that is, the classic behaviourist approach). Early voices such as Kuhlthau's (1993), which present information-seeking as a process of seeking meaning, were at first largely ignored in practice. In recent years there have been intensified efforts to ensure that people who are teaching information literacy adopt constructivist approaches (e.g. Todd, 2001). Limberg (2007) asserts that to learn is not to receive knowledge and information, but is about changing the relationship between a person and the world. She claims that information-seeking is too often focussed on teaching technical procedures and on fact-finding rather than on students formulating authentic questions and constructing their own positions. The concept of authenticity is central to Limberg's ideas on information literacy. Contrived questions and tasks, designed solely to meet externally imposed assessment and with no other consequences for the student, will not engage and motivate students. Without a real and personal interest, students will be satisfied with the superficial answer, the first 'hit', or 'good enough' information. There is no incentive to go beyond using technical skills to collect facts.

Again, the latest outputs from the USA-based Center for International Scholarship in School Libraries (Kuhlthau and others, 2007) focus on the concept of 'guided inquiry' as the basis for teaching and learning of information skills. The main characteristics of guided inquiry are:

- active engagement by students in the learning process
- students building on what they already know
- high levels of reflection
- a recognition of the importance of social interaction and of students' different ways of learning

  (Kuhlthau and Todd 2007)

All these are recognisable characteristics of learning as construction (see, for example, Papert and Harel, 1991). There is little doubt that constructivist approaches are particularly suited to

Web 2.0 tools. In this environment, students can construct artefacts such as video presentations, blog entries and wiki pages both individually and collaboratively. Teachers can join in with collaborative editing and can scaffold students' work. It seems likely that the constructivist approach to teaching and learning so well supported by Web 2.0 tools may finally lead to information literacy teaching becoming more attuned to how students learn.

If constructivist principles are used to inform and guide information literacy work, students will be required to develop a repertoire of strategies that are conspicuously absent from most information literacy models. This will involve:

- reflection: the ability to reflect constructively and to use that reflection in planning for their own development
- evaluation of the processes undertaken as well as of the products of their study
- making sense (deep understanding) of the information that they obtain, linked to the ability to transform the information to reflect their own emerging views

We do not think that these aspects of learning can simply be grafted onto existing frameworks or inserted after any particular element of a linear, sequential model. They are part of an iterative process of learning not well represented in existing information literacy frameworks.

THE IMPORTANCE OF CONTEXT

The importance of context in relation to information behaviour is well established (e.g. Streatfield and Wilson, 1980; Dervin, 1992; Ingwersen and Jarvelin, 2005). Context in information-related behaviour is recognised as multi-dimensional: with different facets reflecting features of the task; characteristics of the learner; and features of the system. Louise Limberg observed in a conference presentation that "Influential studies have abandoned the idea of information literacy as a set of generic skills applied anywhere. Information literacy is not generic but should be seen as social practice …" (Limberg, 2007). Looking at secondary schools, Williams and Wavell (2007) warned that if we are trying to to develop pupils' information literacy we cannot ignore content in favour of technicalities and procedures - if we do so, we will get trivial learning outcomes. Nevertheless, as we have already noted, information literacy advocates have persisted in offering generic skills development frameworks that take little no account of context.

How can the importance of context be reflected in an information literacy framework? We believe that a different type of framework is needed; one that moves away from offering a list of abilities to be taught or applied in an unvarying sequence, irrespective of context.

Alongside the challenge of producing an appropriate information literacy framework we face another problem: how can we teach information literacy in ways that respect the influence of context? Current views on skills development (e.g. Luke, 2006; Williams and Wavell, 2006) assert that if students are to develop their information-related skills through assignments there is a need for:

- Authentic tasks that are recognised as relevant by the students (tasks that have meaning to students on a personal or academic level; not contrived to allow them to practice particular skills)
- Immersion in authentic contexts (realistic environments, current information drawn from the real world, engagement with real world problems and concerns)
- High quality tasks related to current academic work (e.g. asking students to conduct critical evaluation of sources to construct a position for an essay, rather than

offering general guidance on evaluating information)
- Learning embedded in the relationships, values and discourse of the learning community (inherently social)
- Timely teacher interventions in order to move learners on at transition points in their work

Web 2.0 can once again be a powerful support for increasing authenticity and enabling the deployment of information literacy strategies in a variety of meaningful contexts. The possibility of a public platform for their work may help students to take more seriously the underlying information literacy processes involved in producing that work.

STUDENT REFLECTION

If we are to take context into account when deciding on information literacy strategies, this immediately introduces the concept of variation. Bowden and Marton (1998) argued that not only do students need to experience variation in order to learn, but they must also explore variation by comparing and analysing their experiences. To do this, students need to:

- actively engage in discussion and reflection about finding and using information in order to uncover variation in their conceptions
- confront variation in their own experience and in the experience of others.
  (Based on Bruce, 2007, pp. 51-52)

Since at least the 1970s, reflection has been seen as a mainstay of learning and this concept has found its way into many models of learning (e.g. Kolb, 1975; Schon, 1983).

Reflection is a particularly important element in developing the processes underpinning learning and is therefore potentially important in any systematic approach to information literacy. Reflection is taken for granted in most models of information literacy or placed at the very end of the process. This approach in not likely to enable the development of the meta-cognitive strategies necessary to perform problem-solving with information. It is likely to be difficult to integrate reflection into existing information literacy frameworks in any meaningful way (see the discussion about constructivism above). The possibilities for learning provided by Web 2.0 may provide a way forward. For example, peer critique and the collaborative production of artefacts may automatically stimulate reflection. If not, engagement in these processes should provide opportunities for a more formal emphasis on reflection as part of information literacy teaching.

COLLABORATIVE LEARNING

Collaborative learning has long been seen as a desirable process: for example, groupwork is a key element of training courses for teachers in all sectors. Web 2.0 tools have turned many students into sophisticated social networkers via YouTube, Facebook, blogs and discussion boards (Ipsos MORI, 2007). The same tools can also be used to facilitate collaboration in formal learning settings, whether the focus is on creating specific interest groups, building learning communities or enabling the collaborative production and editing of artefacts.

Collaborative learning requires many skills of communication and interaction, but does it make fundamentally different information literacy demands on learners than those made when individually finding and using information? There is little in recent research to indicate that this is the case (Williams and Wavell, 2007; Kuhlthau, 2007). The influence of context (subject, learner characteristics and teacher expectations) is not just about whether students are working individually or in groups to find and use information. At the same time, Web 2.0 can be seen as working counter to collaboration through increased personalisation of learning paths. Overall, this aspect of Web 2.0 raises important issues in the wider context of approaches to learning by providing increased scope for a variety of activities. It may offer valuable avenues for the teaching of information literacy but does not seem to fundamentally affect the information handling skills required.

LEARNERS' EXPECTATIONS OF INFORMATION

Web 2.0 inevitably raises questions of ownership and authority of information. It is an environment in the course of creation by its participants. These participants individually and collaboratively generate content in a form, format and structure that best suits their own needs and preferences. This process works well when the primary focus is on participation in social networks or developing personal interests. However, it can create major difficulties when the same processes are applied in formal learning. Keen (2007) claims that we are diving headlong into an age of mass mediocrity because of the absence of gatekeeper expertise and the increase in user-created content. This view is echoed by Gorman in his Britannica Blog (2007) which identifies an erosion of traditional respect for authenticity and expertise in a world in which everyone is an expert "ignorant of the knowledge they will never acquire and the rich world of learning that search engines cannot currently deliver to them."

Most students should be able to operate both in the social world of web 2.0 and in more formal learning environments (even before we take account of the growing presence of academic interests and institutions on Web 2.0). However, to operate effectively in formal learning environments, student autonomy may have to give way to recognised academic authority. Students' preferred use of Wikipedia and social bookmarking, alongside their facility in creating new 'knowledge' through remixing text, image and audio, or through the collaborative creation and editing of web pages may come into conflict with the necessity to conform to academic norms of using externally-validated information. Students will not be able to simply replicate their social/leisure on-line behaviour when engaging in formal academic tasks. Information literacy should help in this arena: traditional information literacy models do focus on evaluating sources of information, on considering authority and credibility. Such an emphasis should raise students' awareness of the problems associated with following their own preferences and concentrating on their own perspectives. A new balance may need to be drawn between encouraging students to use the range of pathways to information that are open to them in Web 2.0 and ensuring that they have the ability to choose the most appropriate for academic study.

However, do we also need to respond more positively to students' expectations of information? Should the information literacy field legitimise elements of students' preferred information-related behaviour? For example, should we ensure that information literacy frameworks encompass such concepts as 'good enough' information, trial and error, and peer 'expertise' rather than focusing primarily on a set of competencies that appear to be designed to turn all learners into systematic researchers, regardless of the task context?

DOES FINDING INFORMATION REALLY MATTER ANY MORE?

One question likely to worry traditional information literacy proponents is whether there will be a continuing need for skills in information seeking, given an information world in which search engines are become increasingly sophisticated and in which Web 2.0 offers a range of enticing alternatives to systematic searching. According to Carol Kuhlthau (2007) what is important in the 21st century is the ability to use information for problem-solving ***not*** "the technology of finding."

IS A NEW MODEL OF INFORMATION LITERACY NEEDED TO MEET THE CHALLENGE OF WEB 2.0?

We are not convinced that the Web 2.0 environment on its own necessitates the development of new sets of abilities for finding and using information. It does, however, move learning into new directions (e.g. increased collaboration, more authentic tasks, peer critique, non-linear aaproaches to information). In doing so, learning with Web 2.0 tools should put increasing pressure on proponents of information literacy to move in the direction of well recognised learning principles and practices. In particular, information literacy can be enhanced in a formal learning environment by exploiting some possibilities offered through Web 2.0 tools:

- Enhanced group work and shared tasks
- Cooperative creation of multi-media artefacts
- Collaborative editing and critiquing
- Searching for information (e.g. using social bookmarking and folksonomies)
- Organising information in new ways (e.g. using tagging)
- Increasing authenticity of work by presenting ideas to others in a more public space and using a wider range of media
- Providing 'just-in-time' scaffolding to support students
- Facilitating student reflection using records of individual and group processes and providing virtual contemplative spaces

None of these aspirations are new to formal education but some have been difficult to achieve hitherto without the benefits of advances in Web 2.0.

If the information literacy community is prepared to design materials, activities and support mechanisms based on the opportunities offered by Web 2.0, can they adapt existing information literacy frameworks to scaffold their work? Is a framework needed at all to enable information literacy development in formal education settings?

Any model or framework will be flawed because it cannot fully take account of the influence of context on information use or the problems inherent in producing any generic view of information literacy. However, whilst doing research and development work in many further and higher education institutions and schools, we have found that staff and students want to put some sort of framework in place. They want a public statement that clarifies what is encompassed by information literacy; a guide to support curriculum planning; and something that students can refer to when doing research and tackling academic tasks.

The following framework (Markless and Streatfield, 2007) was originally designed to address problems being encountered by the University of Hertfordshire. The University was trying to develop an institution-wide approach to supporting students when finding and using information in an electronic environment. At first it was thought that an existing framework could be used or adapted to meet the needs of staff and students. However, consideration of the issues explored in this chapter made the shortcomings of such an approach apparent. We concluded that many of the traditional information literacy models had been built on a series of assumptions about learning and information behaviour that were problematic and that the increasing use of Web 2.0 threw these assumptions into stark relief. We therefore needed to offer a different solution that is more in keeping with the changing learning environment.

The solution offered is essentially a framework to support student choice in learning rather than information literacy teaching. The framework is designed to enable students to get help where and from whom they need it rather than to usher them through a regimented programme of information skills development. Some of the individual elements of the framework hark back to those designed in the 1980s and 90s. The skills and strategies included are not all new, although we have moved away from a heavy emphasis on systematic searching. In addition this framework is designed to be approached and used differently from traditional frameworks such as the Big6. The drivers behind our approach are student choice and reflection to support effective learning rather than laying out a sequence of steps to be taught.

During three key stages (which do tend towards the sequential) students ***choose*** which strategy to adopt at different points in their research. Help and guidance is available for each of the key elements. Importantly, if one avenue fails students can go back to the big picture and choose another route; they are not trapped in a sequence that they are expected to follow. The framework is designed for students to construct their own problem-solving approaches to finding and using information, either individually or collaboratively. The impact of context on learning should lead students to make different choices about which strategies to employ and which skills to draw on depending upon the nature of the task they are addressing and the wider social context in which they are operating. The framework is designed to take advantage of technological developments that allow individuals to make choices, navigate between options and then save their search paths for future reflection.

The framework that we designed drew on two research-based published models, a non-linear model of information-seeking behaviour[2] devised by Allen Foster (2004; 2006) and a model of information and critical literacies offered by Ross Todd (2001). Foster worked with academics to show the fallacies inherent in the assumption that researchers looked for information using a fixed sequence of steps. Todd's overview of information literacy emphasised transformation and construction of knowledge because he wanted to encourage students to stop interpreting research tasks or assignments merely as processes of collecting information. Instead they are encouraged to think in terms of forming their own perspectives, creating new insights and presenting their own authentic voices.

Our new framework builds on these ideas as well as addressing some of the concerns discussed earlier in this chapter. It is presented below as a series of figures.

Figure 1 provides students with an overview of what is involved with finding and using information. It was important to avoid the trap of presenting information literacy as a series of steps (anything between 5 and 12 stages in many traditional frameworks. The Big6 actually contains 12 steps as there are two stages in each of the 6 main elements of the framework.) Students can choose to engage in any one of the 3 main elements depending on the nature of the academic task they are tackling.

Figures 2, 3 and 4 are what the students see when they click on the relevant box in figure one. There is no set path through any of these figures; if the student is at the beginning of a project they may look at figure two and decide that the best place to begin is with networking. If they click on networking they will get some ideas about who they might contact and how they might work with peers. Equally, a student might decide to begin with problem definition. Again, this element is populated with activities, ideas and advice about how to analyse a problem. Whatever path a student or group of students decides to take through this framework they are offered on-line support at the point of need. They are also encouraged to save their path so that they can see how they worked through a particular assignment - the choices they made. Students compare their chosen paths

Figure 1.

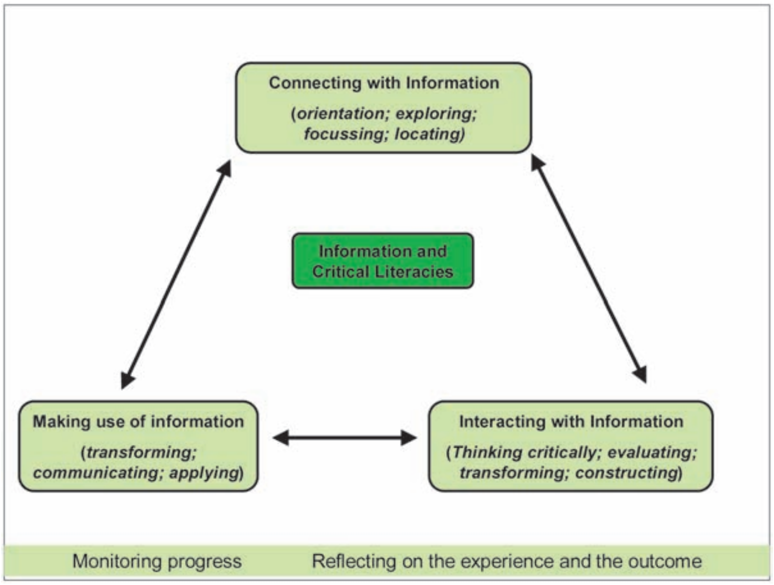

Figure 2.

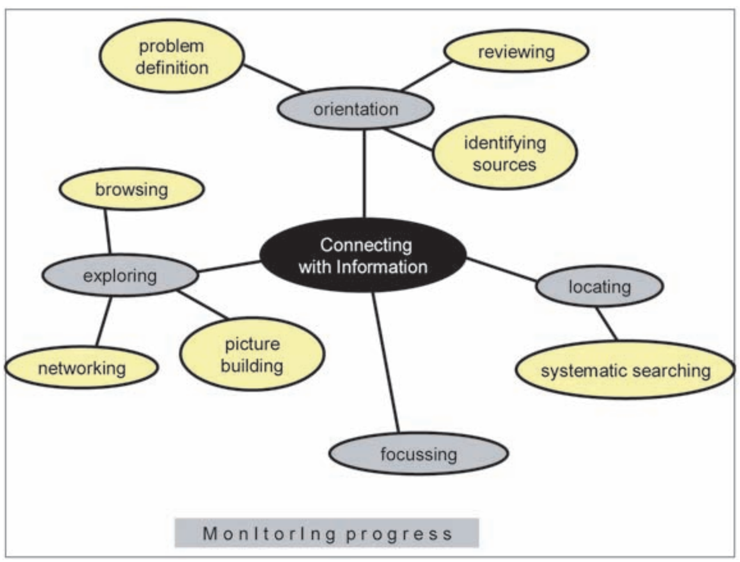

with those of their peers and consider which have been most effective. They can also review their approaches across a number of different tasks to see whether and how they have adapted their approach to the context. Encouraging reflection on the process of learning was an important element in our design of a non-sequential framework.

Where our framework is being used, each element is being populated with material designed by both academic staff and librarians. The framework itself has stimulated some useful collaborative work between staff interested in specific elements most relevant to their discipline. Their aim is to provide support for students who want to use

Figure 3.

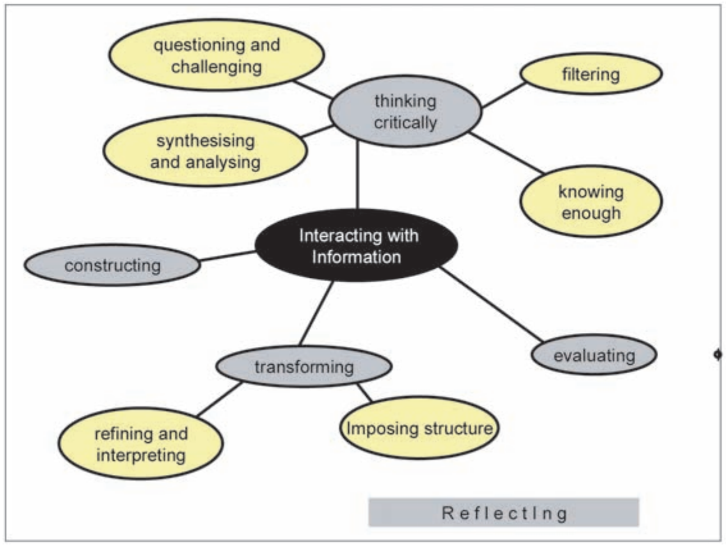

Figure 4.

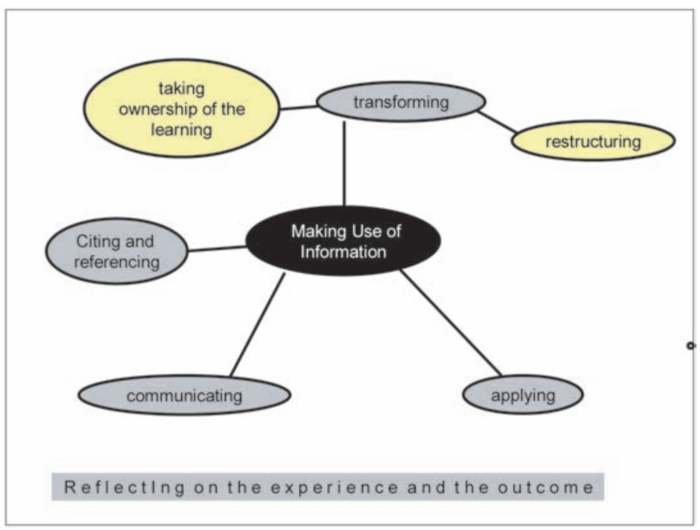

a particular information skill or strategy in the course of their academic work without dictating a path through that work.

This framework is very much a work in progress. It is being tested at universities in the UK and Spain and is currently being translated into Arabic. The real test for this framework will be if students do not see it as a straightjacket, constraining their normal interactions with information, but find it useful no matter what the information environment in which they are working.

CONCLUSION

The traditional information skills models (such as the Big6) that grew out of early interest in enhancing the use of libraries and text-based resources tended to be based on a simplistic view of learning and information behaviour. These models served a purpose in introducing students to the formal world of academic information and, as such, continued to be of use when responding to the arrival of the Internet in its original conception as an information storage and transmission vehicle. However, the shift in focus towards ever greater information access through the Internet combined with greater attention to teaching and learning of information literacy based on constructivist education principles, has led to the traditional information skills approaches being increasingly questioned.

The changes being brought about by the advent of Web 2.0 have served both to provide a further challenge to traditional approaches to information literacy and potential solutions to some of the inherent problems in traditional approaches. The value of teacher-led, text-focussed, sequential models must now be in question because they are based on very un-web 2.0 propositions. Instead, the social networking possibilities offered by Web 2.0 provide fresh opportunities for supporting social learning, including peer information seeking, evaluation, critique of strategies and capturing of processes when helping students to engage with information literacy development. Accordingly, a new framework is tentatively offered here as an alternative to the Big6 and similar models, with the intention of allowing students to construct and revisit their own paths to information discovery, organisation, sense-making and exploitation in the evolving world of Web 2.0.

KEY TERMS AND DEFINITIONS

Constructivist Learning: Learning as an individual or social act of construction, leading to sense-making and the building of meaning.

Information Literacy: A set of abilities for seeking and using information in purposeful ways related to task, situation and context. (Limberg, 2007)

Information Skills: The sets of skills and competencies required to find and use information, usually in a formal education context.

ENDNOTES

1. This observation is based on our experience over twenty years of observing information skills/ literacy lessons and examining lesson plans.
2. Although Foster describes his model as non-linear, it may be more helpful to regard it as a non-sequential model

This work was previously published in the Handbook of Research on Social Software and Developing Community Ontologies, edited by S. Hatzipanagos and S. Warburton, pp. 316-334, copyright 2009 by Information Science Reference (an imprint of IGI Global).

Chapter 7.16
Aspect-Oriented Framework for Web Services (AoF4WS): Introduction and Two Example Case Studies

Ghita Kouadri Mostefaoui
Oxford University Computing Laboratory, UK

Zakaria Maamar
Zayed University, UAE

Nanjangud C. Narendra
IBM India Research Lab, India

ABSTRACT

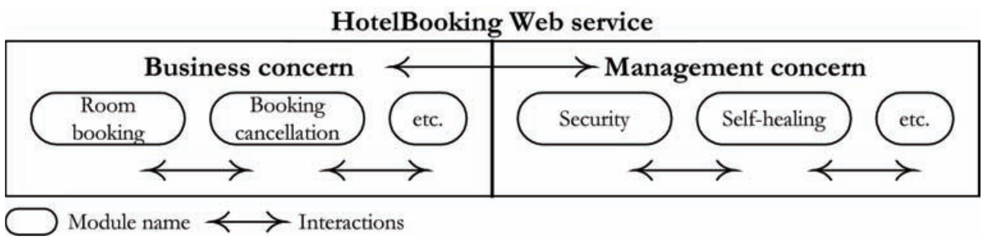
This chapter presents our research initiative known as aspect-oriented framework for Web services (AoF4WS). This initiative looks into the role of aspect-oriented programming in enhancing Web services with nonfunctional properties that are orthogonal to the primary functional properties of Web services, without the need for extensive reprogramming. This enhancement achieves a separation between the functional and nonfunctional aspects of Web services, thereby resulting in easier adaptability and maintainability. We have initially chosen to focus on security and self-healing nonfunctional requirements. The AoF4WS initiative is therefore demonstrated using two projects, SC-WS and SH-WS, which respectively stand for security concerns of Web services and self-healing Web services. Our contributions are relevant to the design phase in an aspect-oriented software development lifecycle.

DOI: 10.4018/978-1-60566-042-4.ch011

INTRODUCTION AND MOTIVATIONS

Web services are an attractive approach for implementing loosely-coupled business processes, which usually spread over companies' boundaries (Ma, 2005). Over the last few years several efforts have been put into the development of standards related to Web services definition, announcement/discovery, and composition, just to cite a few. The dynamic nature of the business world highlights the continuous pressure on businesses to reduce expenses, increase revenues, generate profits, and

Figure 1. Concern separation in a Web service



remain competitive. This calls for a quick reaction to the market trends, a quick handling of users' needs, a quick adaptation to unforeseen changes, and last but not least, a quick understanding of forthcoming challenges. To boost the acceptance level of Web services by the IT community as the technology of choice when developing flexible processes, Web services need to adapt to changing nonfunctional requirements with minimal reprogramming and minimal maintenance effort, so that they can be kept independent from the core Web services functionality. Security and self-healing are samples of nonfunctional requirements, and we will be highlighting them in this chapter.

Integrating security and self-healing capabilities into Web services calls for a clear separation between "business" and "management" concerns along which a Web service is defined (Figure 1). For this purpose, we adopt an aspect-oriented programming (AOP) approach to specify and implement this separation (Cottenier & Elrad, 2004; El-Manzalawy, 2005). This approach is part of our long-term research initiative known as aspect-oriented framework for Web services (**AoF4WS**). This initiative aims at examining the role of aspects in decoupling various concerns in Web services like security and self-healing. The separation between "business" and "management" sides emphasizes the noninvasive requirement that needs to be taken into consideration during the development cycle of a nonfunctional requirement. The mechanisms related, for instance, to security should be confined into one module and thus, should not scatter over the rest of modules of the Web service. Figure 1 illustrates the way concern separation occurs in a fictive Web service referred to as HotelBooking. The business side focuses on details directly related to hotel booking, like checking room availability, rate verification, and confirming client reservation. The management side of a Web service gathers all modules, such as security, self-healing, and monitoring that back the operations of this Web service. Constituents of the management side to be implemented as aspects need to be factored out of the core logic of the Web service.

In the following, we describe the two projects that we have chosen as part of the Ao4FWS initiative. The SC-WS project stands for security concerns of Web services and the SH-WS project stands for self-healing Web services. In Section 2 we present some basic definitions necessary for understanding the chapter. A motivating scenario is also presented in this section. SC-WS and SH-WS projects are described in Section 3 and Section 4, respectively. The chapter concludes in Section 5.

BACKGROUND

Some Definitions

Web Service

For the World Wide Web Consortium (W3C), a Web service is a software application identified by a URI, whose interfaces and binding are capable of being defined, described, and discovered by XML artifacts and supports direct interactions with other software applications using XML-based messages via Internet-based applications. Several standards are associated with Web services like ebXML registry services, Web service description language (WSDL), universal description, discovery, and integration (UDDI), simple object access protocol (SOAP), and WS-security (WSS).

Aspect-Oriented Programming

Ortiz, Hernández, and Clemente (2004a) define aspects as units of encapsulation that are built upon two elements: join points and advices. Join points determine the places or pointcuts where the behavior alteration of an application will happen, and advices identify the new code to be injected in response to this alteration. Aspect-oriented programming has emerged as a programming paradigm that allows gathering of a concern code into one single module. Security, performance, and logging are examples of such concerns that need to be separated from the code of the core application. This approach provides a clean separation between functional and nonfunctional concerns allowing fast update and maintenance of the application code.

Aspect-Oriented Programming for Web Services

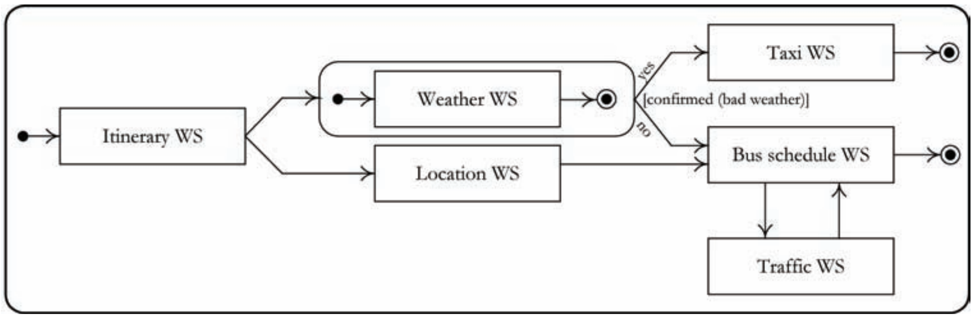
Cibrán and Verheecke (2003) promote modularizing Web services management with AOP. That was motivated because of the hard-wiring technique that is nowadays used for integrating Web services into applications. Hard-coding has several deficiencies when it comes to working out how to adapt to changes, what if a service or network fails, and how to deal with issues related to peers, such as checking for availability, switching to other services, and so forth. Charfi and Mezini (2004) apply AOP to workflow languages like business process execution language for Web services (BPEL4WS) in order to achieve modular and dynamic adaptability of Web services composition. This is done using aspect-oriented BPEL (AO4BPEL), which extends BPEL with additional features that permit, for instance, viewing business rules as aspects. In another work, Ortiz Hernández, and Clemente (2004b) adopt an aspect-oriented approach to develop solutions for Web services composition (of type orchestration) and interaction patterns. Their work was motivated by the lack of standards associated with composition. More particularly, Ortiz et al. raised multiple questions related, for instance, to the possibility of reusing interaction patterns previously implemented, and the efforts to put in for modularizing these patterns rather than scattering the code.

Motivating Scenario

In the following, we detail a motivating scenario, trip composite service (T-CS_1), that will be used for illustrating the two projects discussed in this chapter. The scenario is about Amin who is visiting Melissa back in her home city, Oslo. They agree to meet in a coffee shop, not far from Melissa's office since she finishes work late on that day. Amin has two options to reach the meeting place, that is, by taxi or by bus. Figure 2 illustrates the specification of Amin scenario using a combination of state chart diagrams and service chart diagrams (Maamar, Benatallah, & Mansoor, 2003).

At his hotel, Amin browses some Web sites about transportation in Oslo. A site has itinerary WS that proposes routes between two specific places, for example, between Amin's hotel and the coffee shop. The proposed routes are subject to weather forecasts: cold weather results in recommending taxis, otherwise public transportations like tramways and buses. Parallel to consulting with weather WS itinerary WS requests details about the origin and destination places using location WS. The use of location WS is highly appreciated by Amin since he is not familiar with the city.

Figure 2. Specification of Amin scenario



In case weather WS forecasts bad weather, a taxi booking is made by taxi WS upon Amin's approval. In case of pleasant day, Amin uses public transportation. The location of both Amin's hotel and coffee shop are submitted to bus schedule WS, which returns, for example, the bus numbers Amin has to ride. Potential traffic jams force bus schedule WS to regularly interact with traffic WS that monitors the status of the traffic network. This status is fed into bus schedule WS so adjustments to bus numbers and correspondences between buses can occur.

SC-WS PROJECT: DECOUPLING SECURITY CONCERNS IN WEB SERVICES

Related Work

The open and dynamic nature of the environment in which Web services operate poses various challenges and threats to their security. New Web services appear while others disappear without prior notice. Furthermore, messages among component Web services of a composite Web service have to be checked for integrity, confidentiality, and authentication purposes. The need to secure Web services is discussed by Moorthy and Gandhirajan (2005), as the use of Web services continues to increase. This increase is dependent on how much Web services are a serious development alternative to other rival middleware like CORBA and RMI. Indeed, some still consider Web services as distributed objects that react upon request only (Birman, 2004). Enhancing Web services with extra capabilities can happen along three perspectives as reported by Maamar, Benslimane, and Narendra (2006). The first perspective is about deploying Web services that assess the environment before they take part in any composition. The second perspective is about reducing the semantic heterogeneity gap between independent Web services that have all agreed to participate in a composition. Finally, the third perspective is about conciliating contextual information of Web services using ontologies.

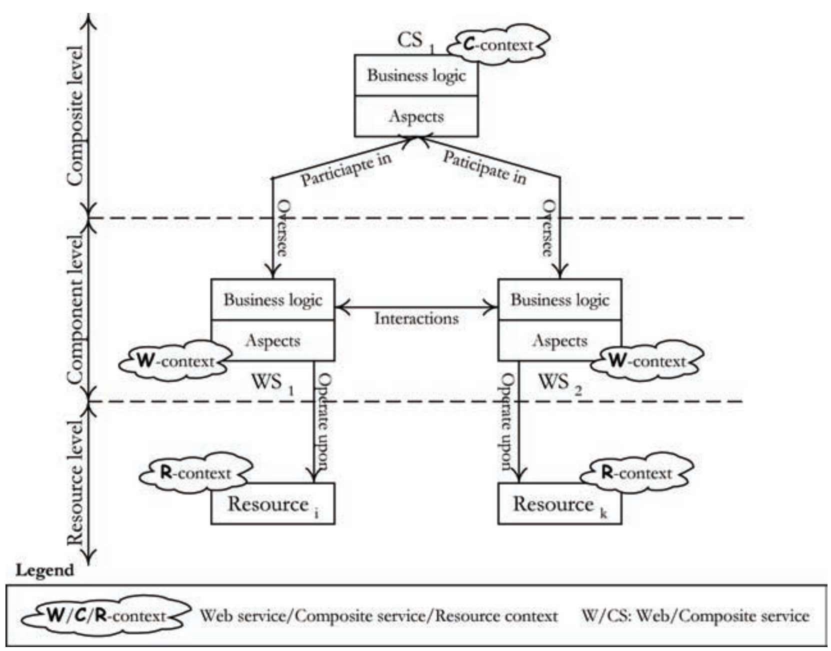
WS-security (2002) is a Microsoft and IBM specification dedicated to Web services security. It is an emerging standard for securing messages among Web services engaged in interactions. For this purpose, WS-security defines how security tokens are contained in SOAP messages. WS-security is extensible to other security models, such as secure sockets layer (SSL), kerberos, and public key infrastructure (PKI). Nowadays, the majority of secure communication measures rely on the transport layer security (TLS). TLS secures interactions by using encryption and makes servers and clients collaborate in order to decide on the authentication process to adopt during data transfer. Unfortunately, TLS does not scale well to complex transactions like those involving Web services (Nakamur, Hada, & Neyma, 2002). Traditional security techniques such as virtual private network (VPN) and SSL cannot secure the large number of requests that Web services expect to receive. The W3C's Web services architecture adopts PKI to secure communications over public networks (W3C, 2005). PKI, however, has a complex infrastructure that negatively affects its deployment cost, processing time, and so forth. Moreover, PKI has the reputation of being quite cumbersome. This could prove to overkill the Web services security to be engaged in intense interactions (Sandhu, 2003). The extensible access control markup language (XACML) is an OASIS standard, which describes both a policy language and an access control decision service interface. A policy is extensible and aims at describing general access control requirements. The request/response style for setting access controls allows forming a query to ask whether or not a given action should be allowed; examples of the queries are permit, deny, indeterminate, or not applicable.

Architecture

Taking into account the context in which Web services operate has been proven to be mandatory when developing Web services. Context-aware Web services result in considering the features of the environment in which the Web services are to be executed (Maamar et al., 2006). These features are multiple and can be related to users (e.g., stationary user, mobile user), their level of expertise (e.g., expert, novice), computing resources (e.g., fixed device, mobile device), time of day (e.g., in the afternoon, in the morning), and so forth. Context is relevant to both functional and nonfunctional properties of Web services.

Figure 3 presents the way aspects are handled in the SC-WS project (Kouadri Mostéfaoui, Maamar, Narendra, & Sattanathan, 2006). Three levels of abstraction exist in this figure: composite, component, and resource. The constituents of each level are related to a particular type of context denoted by C-context, W-context, and R-context, respectively. The rationale of each context

Figure 3. Overview of the SC-WS architecture



type is given by Maamar, Kouadri Mostefaoui, & Mahmoud (2005). The connection between composite, component, and resource levels is implemented with "participate in," "oversee," and "operate upon" relationships, respectively. Some key features of the SC-WS project are as follows: multilevel concern separation using aspects, and contextual tracking of the security requirements of Web services.

The composite level is about context-aware specifications of composite Web services. Each specification is split into two parts: business logic and aspects. The business-logic part reflects the overall objective that the composite Web service has to reach (e.g., hotel booking) using a set of component Web services. The aspect part reflects the cross-cutting concerns that are included in the operation of the composite Web service, and which are orthogonal to this overall objective. The business logic specifies the process by which user functional requirements are met, whereas aspects model user nonfunctional requirements such as security and reliability.

The component level is about context-aware Web services. Similar considerations apply to Web services, which are split into two parts: business logic and aspects. The business-logic part shows the actions that a component Web service has to individually or collectively carry out in order to enable reaching the composite Web service's overall objective. The aspect part shows the nonfunctional requirements that manifest themselves as cross-cutting concerns affecting the actions and interactions of the Web service.

The resource level is about context-aware resources. Resources represent the computing means on which Web services operate. The scheduling of execution requests of Web services is prioritized when enough resources are not available to satisfy them all at once. Moreover, resource allocation to Web services is subject to the context in which the Web services evolve. For instance, the computing requirements of a Web service need to be checked against the computing capabilities of the resources prior to performing resource allocation.

Configuration of Security Aspects

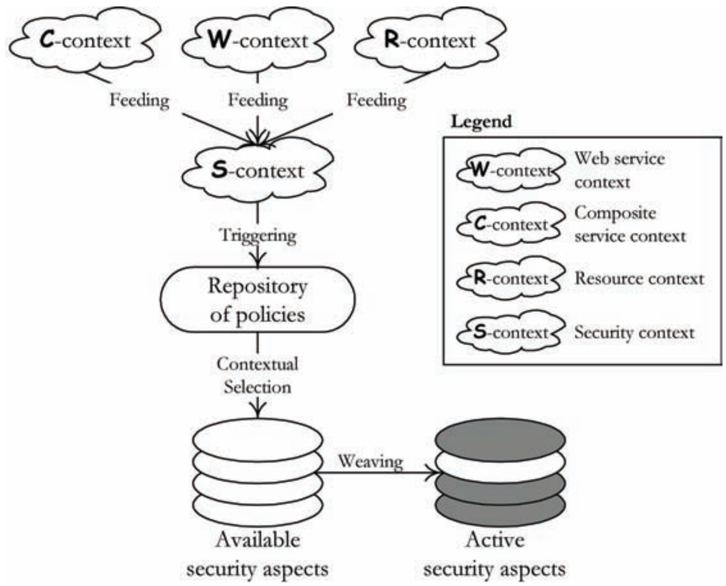
The development of the SC-WS project happened along two dimensions. The first dimension is the need for an adaptive approach that triggers security services (to be implemented as aspects) upon request. For instance, in a specific situation, only authentication aspect is activated, while an extra-logging aspect is activated in another situation. We refer to this dimension in the SC-WS development as composite configuration. It only targets the composite Web services. The second dimension shows the need for a fine tuning of each security aspect associated with composite configuration. For instance, the authentication aspect can be set to accept a timeout of 10 seconds when requesting clients' credentials. We refer to this dimension in the SC-WS development as component configuration. It only targets Web services.

The identification of a configuration that includes both composite and component levels calls for an additional technology to support aspect-oriented programming in modularizing cross-cutting concerns at each level. This technology corresponds to frames. Frames permit achieving this support and are defined as wrappers around code snippets (e.g., source code, HTML code). A frame contains variation points that permit adding, deleting, or adapting functionality in a specific application. This happens using various commands like overriding, extension, substitution, selection, and iteration.

Composite Configuration of Security Aspects

Figure 4 illustrates the operation of the SC-WS project in a configuration of type composite. This operation consists of selecting the security aspects that should be able to protect the whole Web services environment (these aspects are referred

Figure 4. Operations in SC-WS

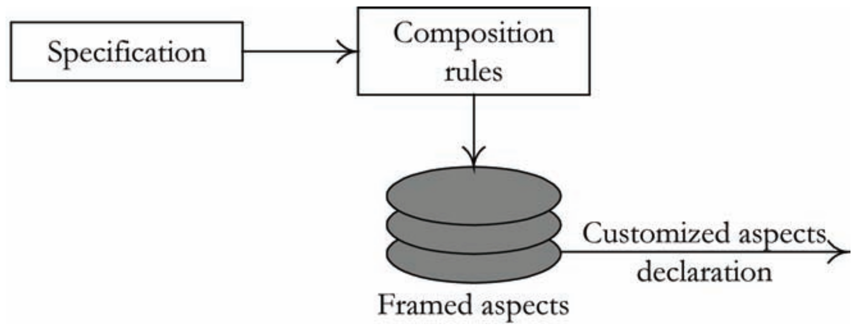


to as active in Figure 4). The selection process combines contextual information and policies. Contextual information offer details on the environment that surrounds each element (e.g., Web service, composite Web service, resource), and policies suggest the appropriate security aspects based on these details.

In addition to W/C/R-contexts of Web services, composite Web services, and resources in the SC-WS project, a new type of context that is just dedicated to security is added (Figure 4). S-context is fed with details obtained out of W/C/R-contexts and gets involved in triggering policies for weaving active security aspects. According to Kouadri Mostéfaoui, a security context is a state of the working environment that requires taking one or more security actions. A security context is formed by a set of information collected from the user's environment and the application environment and that is relevant to the security infrastructure of both the user and the application (Kouadri Mostéfaoui, 2004). In Figure 4, the feeding process is an event-trigger system that gathers contextual information from appropriate sources like contexts of Web services and contexts of resources. Additional sources could be used for feeding the security context, such as physical sensors in the environment or user inputs (Schmidt, Beigl, & Gellersen, 1999). Based on the content validity of each context, policies are triggered. In the following, and relying on a previous work by Sattanathan, Narendra, and Maamar (2005), we overview some arguments that populate each type of context and illustrate the specification of a policy in Ponder. We have selected Ponder due to its expressiveness and ease of use (Damianou, Dulay, Lupu, & Sloman, (2001).

Some arguments in W-context are: signature (establishes the identity of the Web service so that messages to peers are identified), security mechanism (sets the encryption/decryption mechanism needed for authenticating messages received from peers), security status (indicates the status of authenticating the received message in terms of success or failure), and violation (indicates the type of security violation that a message was subject to). Arguments in C-context are similar to arguments of W-context but are interpreted at the composition level. Some arguments in R-context are: signature (establishes the identity of the Web

Figure 5. Framed security aspects generation



service that operates on top of the resource), and violation (indicates the type of security violation that the Web service is involved in). Finally some arguments in S-context are as follows: signature per Web service/composite Web service/resource, security mechanism per Web service/composite Web service/resource, security status per Web service/composite Web service/resource, and security violation per Web service/composite Web service/resource. The main role of S-context is to report on which authentication mechanisms (i.e., username/password pairs, binary certificate, etc.), certificate algorithms, and so forth are supported by all components, whether Web service, composite Web service, or resource, and when they are active.

Policies are information which can be used to modify the behavior of a system (Lupu & Sloman, 1999). The use of policies in the SC-WS project permits managing Web services at a higher level where guidelines for conducting composition of Web services are separated from guidelines for securing Web services. The following is a policy in Ponder that authorizes activating a certain security aspect following the invocation request that a Web service (WS_1) receives from a peer (WS_2). This security aspect depends on the types of authentication and encryption mechanisms featuring WS_2. In this policy, details about these mechanisms are available in the S-context of WS_2 .

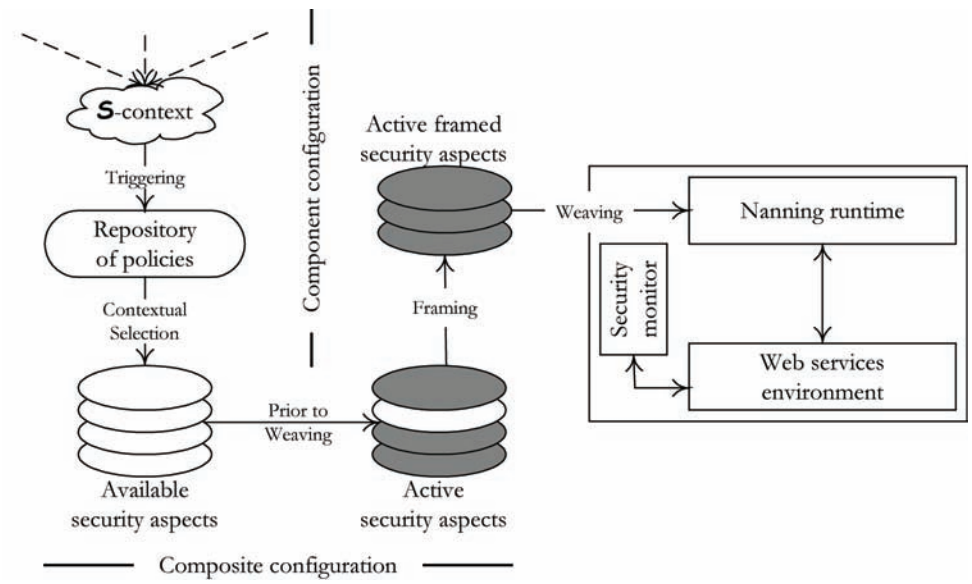
```
inst oblig AuthorizeWS2{
on ServiceRequest(s,t);
when S-context.
authentication(s,"Kerberos",1) and S-con-
text.encryption (s,"DES",1)
subject s = / WS2;
target t = /WS1;
action t.activate(aspecti);
```

Component Configuration of Security Aspects

Figure 5 illustrates the operation of the AoF4WS in a configuration of type component. This configuration aims at supporting the customization of each active-security aspect that was identified in composite configuration and according to the requirements that a user sets. This is achieved using frames. Some examples of user requirements are authentication to happen within 10 seconds and AES-128 is the encryption algorithm. In Figure 5, we also present the way a customized aspect is defined, which is adapted from Greenwood and Blair (2004):

- **Specification:** It is about the developer's security specification to be customized. This consists of setting the values of the metavariables and selecting the different options available in the framed aspect. For example, a specification sets the concrete

Figure 6. Composite and component configuration of security aspects



value of a timeout variable that is contained in a framed authentication aspect code.

- **Composition rules:** They control the way aspects are bound together. For example, an aspect's parameter (e.g., timeout) already defined in the specification can be constrained to a specific interval. The weaving process will then occur upon these constraints.
- **Framed aspect:** It is a parameterized version of the original security aspect that was established in the configuration of type composite. In addition to the generalized aspect code that a famed aspect contains, more elements are added, such as conditional compilation and parameterization.

The reader may wonder about the relationship between policies defined earlier and composition rules. Policies are responsible for selecting security aspects to be activated according to the current context of the whole Web services environment. A composition rule defines how the selected security aspects will be woven in order to secure specific Web services. A composition rule is seen as a policy at the micro level of the aspect. The composition rules apply to the set of aspects once these aspects are selected and customized following their respective specifications.

Putting it all Together

In previous contributions (e.g., Greenwood & Blair, 2004; Loughran & Rashid, 2003), weaving of aspects—for generic applications—is based on a simple schema, that is, on the adaptation of the aspects at the composite level (see above for more details on composite configuration of security aspects). The SC-WS—more specific to Web services—adds an extra step that consists of running an adaptation at the component level by integrating a set of relevant contextual information. Compared to Figure 5, Figure 6 illustrates the operation of the SC-WS after combining composite and component configuration. The new elements in the SC-WS are as follows:

- **Web services environment:** Includes the different component Web services of a composite Web service.

- **Security monitor:** Provides the right set of configured security aspects to the Web services environment.
- **Nanning runtime:** Is based on the Nanning runtime tool (nanning.codehaus.org/) for runtime weaving of security aspects. AspectWerkz, JAC, JAsCo, AOPAlliance, and Prose are examples of other weaving tools.

Figure 6 shows the overall picture of the SC-WS in operation. A transaction in the Web services environment (e.g., a request to use a Web service's functionality) requires from the security monitor to set the needed security aspects (i.e., a request is automatically forwarded to the security monitor before being fulfilled). Component and composite configurations of the AoF4WS engage in collaboration to fulfill this transaction. In the first step, that is, composite configuration, a list of security aspects (e.g., authentication, logging) that need to be included in the security framework is produced. The selected security aspects are then framed in the second step, that is, component configuration. The second step is about how each single aspect will be customized in order to properly respond to the context of use (e.g., type of protocol used by the privacy service). The final set of framed aspects is then concretely woven using Nanning runtime and applied in order to secure the transactions in the Web services environment.

Illustration using Amin Scenario

Refer to Figure 2 for a specification of the Amin scenario. The T-CS_1 puts together an itinerary for Amin. Two of the most significant component Web services of T-CS_1 are taxi booking Web service (TB-WS_1) and bus schedule Web service (BS-WS_2). In the C-context of T-CS_1, Blowfish algorithm is set as part of the security mechanism. In the W-contexts of TB-WS_1 and BS-WS_2, DES and AES algorithms are set, respectively. TB-WS_1 uses a resource, which is an online database through which up-to-date information on available taxis are provided. In the R-context of this database, authentication information is presented so TB-WS_1 gets to access this database.

Based on the W/C/R-contexts discussed earlier, the S-context arguments of T-CS_1 are instantiated. Some of them are: DES algorithm for BS-WS_2, Blowfish algorithm for T-CS_1, security status for TB-WS_1 accessing the database resource ("access granted"), and security violation (if any has occurred; in our case, so far, no). The S-context information is then used to populate the policy repository with the appropriate policies. A sample of policy is to authorize the invocation of TB-WS_1 upon request of T-CS_1, assuming that the security conditions are met.

```
inst oblig AuthorizeTaxiWebService{
on ServiceRequest(s,t);
when S-context.
authentication(s,"Blowfish",1) and S-con-
text.encryption(t,"DES",1)
subject s = /T_CS1;
target t= /TB_WS1;
action s.invoke(t);
```

In other words, when trip Web service authenticates itself to taxi service, this latter is supposed to accept the invocation request from trip service. A similar bus schedule request can also happen, as shown below.

```
inst oblig AuthorizeBusScheduleWebSer-
vice{
on ServiceRequest(s,t);
when S-context.
authentication(s,"Blowfish",1) and S-con-
text.encryption(t,"AES",1)
subject s = /T_CS1;
target t= /BS_WS2;
action s.invoke(t);
```

Based on the policies defined above, the list of appropriate security aspects is generated (i.e., DES aspect, Blowfish aspect, and AES aspect). Since the above policies are needed for Amin, the appropriate authentication code is weaved into the respective Web services (TB-WS_1 and BS-WS_2) in order to ensure that the necessary security checks are carried out during the composition of these Web services. The actual weaving itself is carried out via frame technology, as follows. Prior to the weaving process, each framed security aspect—identified by the list generated earlier—is customized according to the values set in the specification, as illustrated in Figure 6 (component configuration of security aspects). Afterwards the framed versions of these framed security aspects are woven using the Nanning runtime.

Summary

In the SC-WS project, we argue for an adaptive security strategy in Web services environments using framed aspects, which are the combination of frames and aspect-oriented programming. Frames enhance aspect-oriented programming by separating the specification of a security aspect from the aspect code itself. This approach allows for a fine-grained variation of security aspects according to the context of use.

SH-WS PROJECT: SELF-HEALING WEB SERVICES

The development of self-healing Web services means enhancing them with self-healing properties, such as how to deal with a timeout response from a critical request and how to resume operation after a major crash. One of the recommendations we put forward while designing and coding self-healing functionalities is to keep them separate from the design and code implementing the business logic of a Web service. Concern separation permits avoiding cross-cutting issues and emphasizes the noninvasive requirement that needs to be integrated into the development strategy of self-healing Web services. The inappropriate handling of this requirement leads into a code that is scattered all over the Web service and, thus, becomes difficult to localize and maintain. This maintenance exercise is extensive, expensive, and error-prone. In this chapter we suggest using aspect-oriented programming to design and develop self-healing Web services. The use of self-healing permits develops Web services that are more agile and robust, responsive to (unpredictable) changes in the environment, thereby resulting in reduced downtime, capable of self-diagnosis, and proactively seeking to avoid "unsafe" configurations. Multiple challenges face the development of self-healing Web services, including how to trigger the self-healing process, how to model and track Web services engaged in self-healing operations, how to adjust control and data flow among these Web services, and how to automatically modify this flow with little disruption.

Related Work

Baresi, Ghezzi, and Guinea (2004) select the selection stage of Web services in order to illustrate the importance of self-healing mechanisms. Shutting-down a system because of a Web service failure is no longer acceptable, whether in critical-systems or not. The execution environment should be able to identify new Web services and even to reorganize the process to find a solution that uses what is available, if a perfect match does not exist. Baresi et al.'s proposal revolves around special-purpose probes, that is, monitors, to allow the execution environment to detect anomalous conditions such as a nonresponding Web service. Their proposal is built-upon two techniques: defensive process design and service runtime monitoring. The approach they follow is mainly based on assertions of prepost and invariant conditions; these facilities are inspired from some programming languages such as Eiffel. The resulting proposal suggests the use of such facilities in order to implement recovery actions at the code level.

Ardissono, Console, Goy, Petrone, Picardi, Segnan, et al. (2005) propose a framework for adding diagnostic capabilities to Web services, using a model-based perspective. The objective is to develop self-healing Web services. The framework associates each Web service with a local diagnoser that relates hypotheses about incorrect outputs of this Web service to misbehavior of the Web service itself, or to incorrect inputs from other peers in composition scenarios. Besides the local diagnoser, a global diagnoser is deployed at the composite level. It coordinates the local diagnosers, exchanging messages with them and sometimes computes diagnoses without relying on the feedback of these local diagnosers. Pencole, Cordier, and Grastien (2005) model Web service workflows as discrete-event systems using a model-based reasoning approach. Such a model is the first step towards tracing the evolution of the workflow and diagnosing faults at run-time. The result is a tool for monitoring and diagnosing Web services.

Although the research outcomes in the above projects are promising, two major concerns still remain to be handled: How do we develop self-healing Web services without altering their underlying code? And how do we interleave monitoring, diagnosis, and adaptation as part of the self-healing process without interrupting the execution of the unaffected Web services? Modularizing both concerns using software engineering techniques like object-oriented is hard to achieve. This is where aspect-oriented programming comes into play, as will be described below.

Monitoring Model

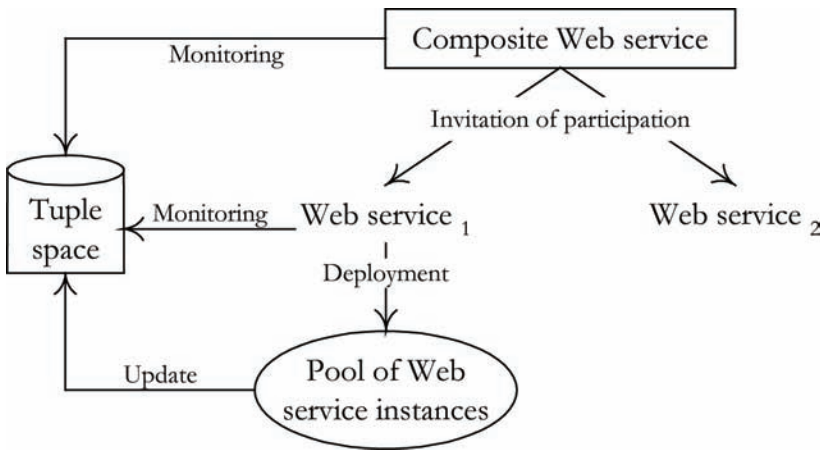
As part of the self-healing process, the ability of Web services to self-coordinate is important, that is, being able to monitor the progress of their execution without the overhead of a centralized coordinator. Of course, the composite Web service can always implement a centralized monitoring. However, this turns out to be a bottleneck to the architecture and imposes an unacceptable performance overhead. A decentralized monitoring model that could also permit centralized monitoring, if needed, is deemed appropriate.

Our monitoring model complies with the distributed tuplespace-based approach described by Maamar, Benslimane, Ghedira, & Mahmoud (2005) and depicted with Figure 7. The lifecycle of the monitoring model highlights the following elements: composite Web service issuing invitations of participation to component Web services, component Web services deploying Web service instances upon invitation acceptance, and monitoring being conducted at composite and component levels.

The operation of the monitoring model of Figure 7 assumes that a Web service instance is self-aware. The Web service instance has access to the description of the specification of the composite Web service. This permits to the Web service instance to know and assess the constraints under which it operates in terms of execution time, execution chronology, and acceptable data, just to cite a few. For monitoring purposes at the Web service level, a Web service instance is supposed to post all its activities on the tuplespace that is connected to its Web service. The composite Web service has all access to the tuplespace subject to some access rights verification. It is interesting to note that any failure or delay is automatically reported in the tuplespace, which permits immediate solutions to be deployed. To keep the chapter self-contained, the way a tuplespace operates is excluded. Readers are referred to Maamar, Benslimane, Ghedira, Mahmoud, and Yahyaoui's (2005) work.

Applied in the Amin scenario, the monitoring step is concretized as the following. When a Web service detects an error within its execution, it raises an exception by updating its respective tuplespace. Upon receipt of the exception, the tuplespace reports it to the rest of participating Web services that have expressed interests in this kind of exception. If bus schedule WS detects an error,

Figure 7. Monitoring model for self-healing Web services



this information will be recorded and propagated as an exception to traffic WS and weather WS.

Diagnosis Model

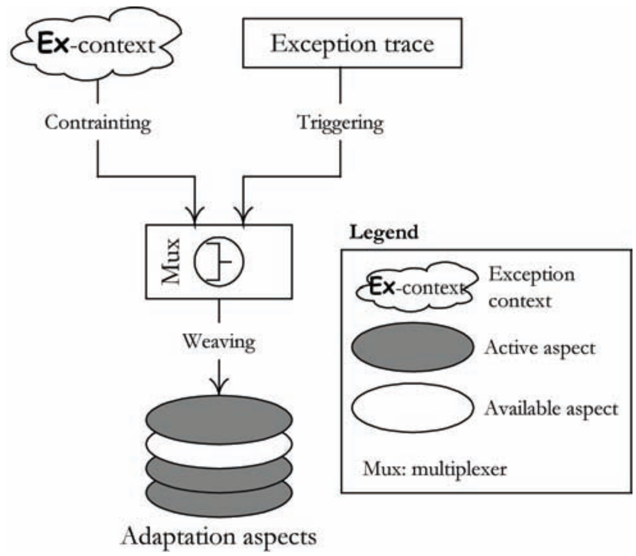
As part of the self-healing process, diagnosis continues monitoring. Diagnosis is the process of discovering the cause and nature of a fault (Ardissono et al., 2005). When a Web service instance fails, the cause can either lie within this Web service instance, or within a peer or resource that the Web service instance in question depends on. In the Amin scenario, if the bus schedule WS signals a failure, two options exist: either the bus schedule WS itself is not able to send the schedule due to an internal error, or the bus schedule WS has not received the right input from the location WS so it can send an appropriate bus schedule to Amin.

Two types of dependency exist between any pair of Web service instances WS-I_i and WS-I_j, where WS-I_j succeeds WS-I_i in the composite Web service specification: control flow and data flow. In a data flow dependency, WS-I_j requires data from WS-I_i in order to execute successfully. For example, the bus schedule WS requires the location data from the location WS so a bus schedule is provided. WS-I_i can create, modify, forward, or consume the data.

- **Data creation:** WS-I_i is the source of the data. WS-I_i is therefore to be diagnosed as the cause of failure since the data are being erroneous.
- **Data modification:** A different Web service instance is the source of the data. This requires checking whether the modification operation implemented by WS-I_i produces the expected result. If so, then the data need to be traced back to their source, in order to determine where the error occurred.
- **Data forwarding without modification:** Another Web service instance WS-I_k before WS-I_i in the composite Web service specification, is the possible failure cause. Therefore, the data should be traced back to their source until the failure-causing Web service instance is identified.
- **Data consumption:** WS-I_i is the final destination of the data that will become an input for the creation/modification of another data variable.

In a control flow dependency, the output of WS-I_i should satisfy certain preconditions that are needed for WS-I_j to execute successfully. In the Amin scenario, the positive confirmation of bad weather is the precondition needed for taxi WS to execute. The precondition value generated by

Figure 8. Aspects during adaptation



WS-I_i is based on the data created/modified by it. In case of any error in this data, for example, wrong confirmation of bad weather, the source would be WS-I_i itself.

The distributed tuplespace supports diagnosis by tracing the execution results in the reverse direction in which the execution occurred, while checking where the control and/or data flow dependencies have been violated. This will stop once all Web services where the data variables have been created have been covered by the tracing process. As described above, the execution results are stored/maintained in the tuplespace, and hence they can be retrieved from there for verification. In the Amin scenario, a partial list of data flow sequences could be: location WS → bus schedule WS, traffic WS → bus schedule WS, and weather WS → bus schedule WS. The consumption of location, traffic, and weather data results in creating the bus schedule for Amin. Any error in bus schedule WS means that the data flow sequences will be traversed in the reverse direction up to the sources of these data and verified to determine where the error occurred. First, the bus schedule calculation is checked; if that is correct, the location/weather/traffic calculations are checked to determine which of these data variables are erroneous. Since these three data variables are created afresh by their respective Web services, the checking will stop there.

Adaptation Model

Having detailed how the monitoring and diagnosis models operate, we discuss hereafter the adaptation as the last step of the self-healing process. The adaptation occurs using what we call exception trace, exception context, and multiplexing aspects (Figure 8). The exception trace relies on the data flow that is stored in the tuplespace and obtained by a reverse analysis of the content of the tuplespace. The exception context is the state of the Web services when the failure occurred. Multiplexing aspects trigger the adaptation actions based on the exception trace and the context.

Web services failures range from internal errors to some other external factors like network congestion. Handling exceptions is then highly dependant on the source and type of failure. To keep track of a failure source and type, an exception trace is generated out of the tuplespace. An effective adaptation strategy should be supported by an appropriate exception handling at the code level. This is dependant on the features of the programming language. In Java, java.lang.Exception and java.lang.RuntimeException packages are dedicated classes for exception handling.

The adaptation strategy we discuss in this chapter relies on the exception and the current context as well. Recovering from a timeout failure when the requested Web service is overloaded may be handled by a retry process. The same exception due to the Web service constant unavailability requires a dynamic binding to another Web service. As a result, Web services should be continually aware of the current context in order to adopt the right strategy for exception handling. The following suggests some examples of contextual elements constraining the adaptation strategy:

- **Exception time:** When the exception was observed.
- **Exception location:** At which point of the Web services composition the exception occurred.
- **Previous exceptions:** Number of times the exceptions were reported at the same point of the Web services composition.

In Figure 8, the multiplexer supports multiplexing aspects. Multiple aspects mean different strategies to adopt for handling different exceptions. Multiplexing is a well-known technique in the field of electrical engineering (Wikipedia, 2005). This technique supports mixing the inputs from multiple sources into one connection. In the self-healing process, multiplexing is used to simultaneously combine exception traces and current exception context so the right self-healing strategy is derived. In order to implement the concept of multiplexing aspects, we follow a policy-based approach. The primary use of policies is to perform actions according to the occurring events and detected changes. Our main motivation in adopting a policy-based approach is to support the adaptation of self-healing actions by taking advantage of the up-to-date information that context caters over occurred exceptions. We use the well-known Ponder language for representing the policies, due to its expressiveness and ease of use (Damianou et al., 2001). We use obligation policies as a class of Ponder policies, which are event-driven condition-action rules for actions that must be performed on specified objects of the target domain. For weather WS, the policy for activating the aspect relating to weather confirmation could be as follows:

```
inst oblig SelfHealing{
on Exception(t);
when context-elt1 = “4 PM” and context-
elt2 = “Weather Confirmation” and con-
text-el3 = “3”
subject t = /WeatherService;
action t.activate(aspecti);}
```

The activation of aspect$_i$ would result in changing weather WS code, so the correct weather information for Amin is recomputed. The contextual elements refer to those listed in the previous table: exception occurred at 4 PM, in weather confirmation module of weather WS, and this is the third time this error occurs. In case the error was in a different module, say, weather information gathered from a satellite imagery, a different aspect other than aspect$_i$ would need to be activated for self-healing purposes.

Summary

As a nonfunctional and must-have property, fault tolerance of Web services has been extensively investigated in the last few years. The focus has been more on error detection and recovery in composite Web services execution flow. In the current chapter, however, we have proposed a reusable framework that achieves self-healing of Web services and allows for consideration of recovery actions as structured units. Implemented as software aspects, the self-healing actions are triggered based on the type of the fault in the composite Web services flow and on the context of use. Our approach aims at separating the fault-tolerance mechanisms from the core code of the Web services in order to allow for a structured and easy maintenance of Web services. We have also positioned our self-healing technique within our previously introduced AoF4WS framework that uses aspects for decoupling various concerns in Web services. Future work will involve developing an implementation to demonstrate our technique.

CONCLUSION

The AoF4WS research initiative is devoted to highlight the added-value of aspect-oriented programming in implementing nonfunctional requirements of Web services. It is also intended to identify the core technologies that realize these requirements. In this chapter, we introduced the AoF4WS initiative that so far encompasses two research projects, namely SC-WS and SH-WS. Both projects use the well-known aspect-oriented programming technique to decouple cross-cutting concerns in Web services. Such a decoupling promotes a clear separation between the operational and nonfunctional aspects of Web service executions, thereby resulting in easier adaptability and maintainability. As a future work, we are looking at extending our framework by tackling other nonfunctional requirements, such as performance. In addition, we will be investigating the issues involved in implementing several aspects simultaneously, which could result in semantic interference between the aspects (Durr, Staijen, Bergmans, & Aksit, 2005).

Chapter 7.17

A Static Web Immune System and its Robustness Analysis

Tao Gong
Donghua University, China & Central South University, China

ABSTRACT

Static Web immune system is an important applicatiion of artificial immune system, and it is also a good platform to develop new immune computing techniques. On the Static Web system, a normal model is proposed with the space property and the time property of each component, in order to identify the normal state of the system that the artificial immune system protects. Based on the normal model, the Static Web immune sytsem is modelled with three tiers, that is the innate immune tier, the adaptive immune tier and the parallel immune tier. All the three tiers are inspired from the natural immune system. On the tri-tier immune model, the self detection mechanism is proposed and programmed based on the normal model, and the non-self detection is based on the self detection. Besides, the recognition of known non-selfs and unknown non-selfs are designed and analyzed. It is showed that the Static Web immune system is effective and useful for both theory and applications.

DOI: 10.4018/978-1-60566-310-4.ch011

A.1 INTRODUCTION

Human immune system is very important for human health, because it is able to detect, recognize, memorize and eliminate foreign viruses and inner faults, which are sometimes unknown and even quite complex (Perelson, Hightower & Forrest, 1996; Fauci, 2003; Chao, Davenport & Forrest, et al, 2004). Inspired from nature, artificial immune system is very important for computer world, because it is used to detect, recognize, learn, memorize and eliminate special objects, which are possibly unknown and even quite complex, such as computer viruses, faults and so on (De Castro & Timmis, 2002; Jerne, 1974; De Castro & Von Zuben, 2002). However, due to incomplete theories of immunology, one of bottlenecks for detecting the unknown non-selfs prevents the artificial immune system from developing. First, traditional detection approaches against viruses and faults are based on matching the features of the viruses and faults, and the features of unknown viruses and unknown faults are possibly unknown, thus 100% detection is impossible in theory (Balachandran, 2005; Gonzalez & Dasgupta, 2003). Second, the faulty mechanism for detecting viruses and faults causes lower possibility for recognizing the viruses and faults, and affects ability and efficiency for repairing the damaged computer system. To overcome the bottleneck of research on the artificial immune system and improve research on the basis of the anti-worm application and software fault diagnosis, a normal model of the static web immune system is proposed and built with the space-time properties of the components, and the normal model is used to represent the selfs.

A.2 BACKGROUND

Web system is popular on the Internet now and useful for many web users, and web security has become a serious problem due to viruses, worms and faults (Balthrop, Forrest & Newman, et al., 2004; Orman, 2003). To solve the security problem, some detecting techniques are used to recognize the non-selfs such as viruses and faults by matching the features of the non-selfs, but the traditional techniques have a difficult bottleneck in detecting unknown non-selfs especially such as brand-new viruses. To overcome the bottleneck, a new strategy for detecting the unknown non-selfs has been proposed with the normal model of the system that the artificial immune system protects. Current work has been done on the static web system and in fact many static web systems are useful and popular on the Internet, such as the webpage system for many companies and universities.

A.2.1 Space Property of Component

Suppose a static web system S is comprised of m web directories and n files in the cyberspace, and the system can be represented with the set

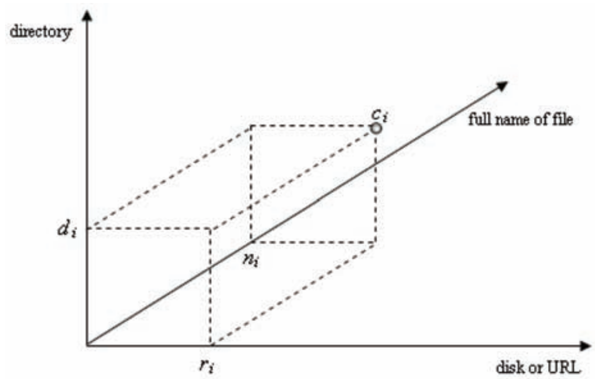
$$\{p_{ij}, d_k | \sum_{i=1}^{m} n_i = n; p_{ij} \in S; j = 1, \cdots, n; k = 1, \cdots, m\}$$

Here, p_{ij} denotes the jth file in the ith directory of the system *S*, dk denotes the kth directory in the system *S*, and ni denotes the sum of all files in the ith directory of the system *S*.

The components of the static web system are software parts, and the software is used to simulate the physical world in the cyberspace. In the physical world, every object has unique 3-dimension space coordinates and 1-dimension time coordinate, so that the state of the object is uniquely identified by its space-time coordinates (Einstein, 1920). Alike in the cyberspace, every software part has unique location for storing the space property because the storage of the software is based on the hardware in the physical world. The absolute pathname pi is used to represent the location information for storing the file and/or the directory, and the pathname consists of the name ri of the disk or the URL, the name di of the directory and the full name ni of the file ci, shown in Figure 1. The full name of the file includes the file-name of the file and the suffix name of the file, and the suffix name of the file is one of features that are useful for classifying the files.

According to the basic rules of the operating systems for managing the files, the absolute pathname of the file c_i uniquely identifies the location

Figure 1. 3-dimension information of the absolute pathname for files. ©2008 Tao Gong. Used with permission.



of the file in the computer. One absolute pathname belongs to only one file at a certain time, and at that time the file has only one absolute pathname.

A.2.2 Time Property of Component

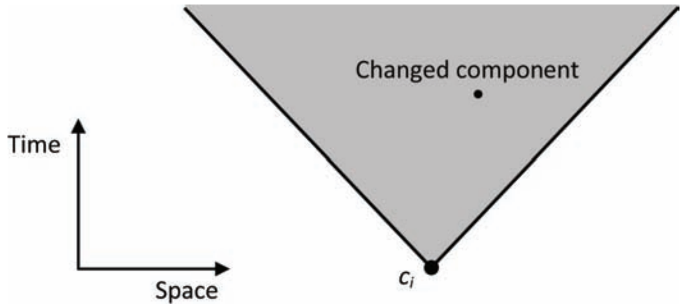
Time property of every object in both the physical world and the software world only has one dimension, and each time variable has four parts: date part, hour part, minute part and second part. However, the time property of natural object in the physical world is not changeable, but the time properties of files in the current operating system are changeable. The operating system is a kind of complex dynamic system in which the normal model is difficult to build. For simplification, the normal model is built for the static web system and the artificial immune system is designed to protect the static web system, because the normal model can be built on the condition that the time property in the static system is unchangeable to keep the normal state.

In general, according to the representing method of time, the data of time includes the data of the date, the data of hour, the data of minute and the data of second. Moreover, if the accuracy for representing the data of time is higher, the data of time may include the data of microsecond and so on.

When a component is changed, the time point of the cyberspace is certainly changed and the change on the component can be external or internal. The external change of the component can be shown with the space property of the component, but the internal change of the component must be detected by the operating system and represented with the time property. In some current operating systems, the change of the component such as file or directory is detected with the function for representing the time that the component has been changed for the last time. The approach may be imperfect, but it is feasible in the static web system on the condition that the operating system is robust. The external change of the component may occur on the disk name of the component, the directory name of the component or the file name of the component, and the future change of the component c_i is shown in Figure 2 (Hawking & Penrose, 1996).

On the other hand, the internal change of the component is affected by many factors such as the structure of the component, the length of the component, the special unit of the component and so on. For example, from the time point t_1 to t_2, the component c_i is changed with its structure into a new component c_j, shown with bigger scale in Figure 3, and the functions of the component will be also changed.

Figure 2. External change of the component c_i. ©2008 Tao Gong. Used with permission.



A.2.3 State of Static Web System

The state of the static web system is either normal or abnormal, and the normal state of the static web system is static. When the static web system is set up for usage, the initial state of the system is normal and the normal state of the static web system can not be transformed into another different normal state. In this chapter, suppose the operating system is always normal, the artificial immune system is designed to protect the static web system so that the static web system can keep normal against worms and software faults.

To keep the normal state of the system, the state of the static web system must be defined as normal or abnormal. The normal state of the static web system is the state that the current system has same structure and components as the initial system. The abnormal state of the static web system is the state that the current system has different structure and components from the initial system.

To describe the state of the static web system, a normal function $N(x)$ is defined as such.

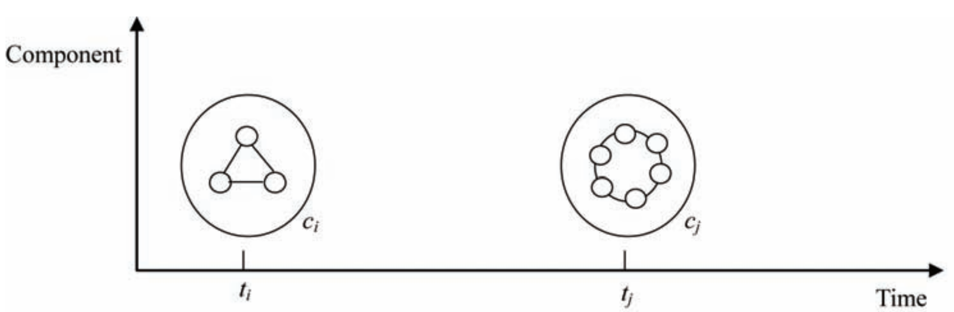
$$N(x) = \begin{cases} 1 & , x \text{ is normal}, \\ 0 & , x \text{ is abnormal}. \end{cases} \tag{1}$$

Here, x is an object in the static web system or the system itself.

Considering the composition of the static web system, the state of the static web system is uniquely identified by the states of the components for the system, and the components of the static system include files and directories. Suppose the state of the component c_i is represented as $N(c_i)$, the state of the system S can also be represented as such.

$$N(S) = \prod_{i=1}^{m+n} N(c_i), \quad c_i \in S. \tag{2}$$

Figure 3. Internal change of the component c_i. ©2008 Tao Gong. Used with permission.



A.2.4 Normal Model of Normal Static Web System

When and only when all the components of the system are normal, the system is normal. If one component among them is abnormal, the system is abnormal. Therefore, if and only if every component of the static normal web system is identified uniquely, the normal state of the static web system can be identified uniquely. The following theorem proves that the normal state of the static web system can be detected with the space-time properties of the components in the system.

Theorem A.1 Suppose a static web system *S* is comprised of *m*+*n* components, each of which has its unique absolute pathname (space property) and unique last revision time (time property). Let the absolute pathname of a component c_i be p_i and the last revision time of the component c_i be t_i. On the condition that the space-time properties of the static web system are correct, the absolute pathnames and last revision time of all the normal components in the normal static web system uniquely identify the normal state of the system.

[Proof] In the static web system there are n+m components of web pages and directories, which uniquely identify the system. Therefore, the normal state of every component in the static web system should be identified with its space property and time property before the whole web system is identified. For a certain absolute pathname p_i, the corresponding component c_i is unique. Moreover, if the last revision time t_i of the component c_i is certain, the current state of the component c_i is also unique. The revision time t_i is recorded when the static web system is normal, so that the component c_i is also normal at that time. Thus, the absolute pathname p_i and the last revision time t_i identify the normal state of the unique component c_i in both the space and time dimensions. For a certain component c_i of the web system *S*, the absolute pathname p_i of the component is unique, because this is kept by the rules for managing files and directories with the operating system. Besides, the revision time of the component c_i is also unique, because the last revision time of every thing should be unique. All in all, the absolute pathname and last revision time of every normal component in the normal static web system identify the normal state of the component. Based on the unique identification between the static web system and its components, the normal state of the static web system is uniquely identified with the absolute pathnames and last revision time of its all normal components. Theorem 1 is correct. ■

The last revision time is a representing parameter for the operating system and the parameter is different in the physical world. When a copy of a component is made in the cyberspace, the copy has same revision time (time property) as the component, so that the copy is called same to the component. In fact, the physical storage of the copy is different from that of the component. In the physical world, no two objects are completely same and the concept of sameness is local and partial. Therefore, the time property of the component shows the partial computing feature of the operating system in the cyberspace.

According to Theorem 1, the normal state of the static web system has three examples. The first example is the initial static web system, and the conclusion is self-evident. The second is the unchanged system after a period, and the space properties and the time properties of all the components in the system are unchanged. Therefore, the state of the current system is same as the initial system, so that the current system is also normal. The third example is the repaired system that was damaged and ever abnormal but now has been repaired by the artificial immune system. When the damaged components are being repaired, the backup components are copied to replace the damaged ones and the backup components have same last revision time as the components that were damaged. Thus, all the components of the repaired system have same space properties and time properties as those of the initial system, and the repaired system has the same state as the initial system.

The normal model of the static web system is a new attempt to build the normal model of the selfs and increase the probability for detecting the non-selfs by detecting the selfs. This work can establish a basis for investigating the approaches to build the normal model of the dynamic system and design more intelligent and effective immune algorithms for real complex systems. To update the normal model for the dynamic systems, the normal models must be adjusted according to some rules and protected by some security techniques.

A.3 TRI-TIER IMMUNE MODEL OF STATIC WEB SYSTEM

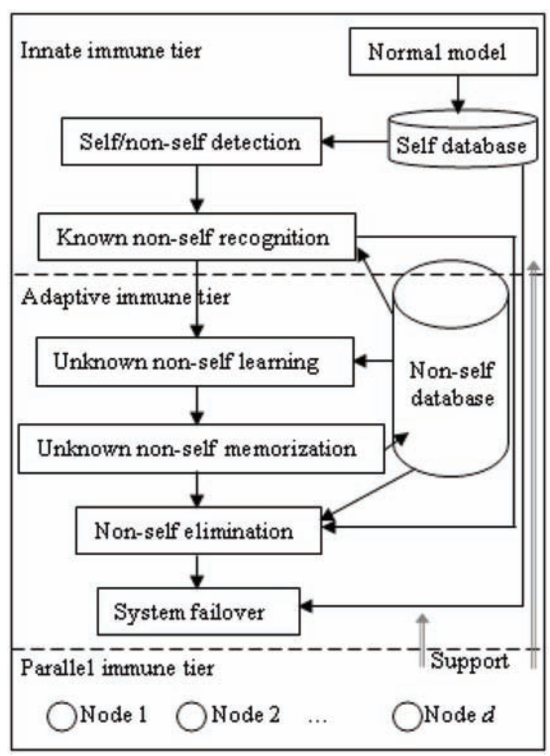
In biological immune systems, the innate immunity and the adaptive immunity are two main types of immunity, which are provided by many immune cells such B-cells and T-cells. The innate immunity is responsible for discriminating the selfs from the non-selfs and recognizing the known non-selfs. The adaptive immunity is responsible for learning unknown non-selfs and memorizing the new known non-selfs that were ever unknown but now known after learning. Based on the mapping model of natural computation, the two types of immunity are mapped to the first tier and the second tier of the immune computing model for the static web immune system. Considering another important trait of processing information in a parallel and distributed way in the biological immune systems, the parallel immune cells is an infrastructure for the immune system. Alike, the parallel computer can provide a powerful computing infrastructure for some complex artificial immune systems, and the parallel computer is used as the third tier of the immune computing tier for the static web immune system.

A.3.1 Tri-Tier Immune Structure

The tri-tier immune computing model of the static web immune system is based on the normal model of the static web system, and the normal model is built with both the space property and the time property of each component in the system. The tri-tier immune computing model is inspired from some natural immune theories, and includes inherent immune tier, adaptive immune tier and parallel immune tier, shown in Figure 4. The parallel immune tier is built on the parallel computing theorems, and used to increase efficiency (Gong & Cai, 2003).

In Figure 4, when the foreign object enters the static web system, the random detectors begin to detect whether the foreign object is self or non-self, by matching the features of the foreign object with

Figure 4. Tri-tier immune computing model of static web immune system. ©2008 Tao Gong. Used with permission.



the self information in the self database. The self is the part of the static web system, such as the webpage files of the static web system. And the non-self is not any part of the static web system or compatible with the static web system. The self information is used to define the features of the self and represent the normal state of the static web system. And all self information is stored in the self database. During the immune process of the artificial immune system, the percent of the selfs is maximized and the amount of the non-selfs in the static web system is minimized. When a foreign object is determined as a non-self, pattern recognition of the non-self is started in two ways. One is the way of matching features, and the other is the way of matching rules. The former is done through querying records in the database and matching the feature information of the detected non-self with the record information in the non-self database, where the entire known non-selfs store. The latter is done in a random way through searching some antibodies in the rule base. If the non-self is known by the artificial immune system, then the destroyer is called to eliminate the non-self. For computer viruses and software faults, the deletion command in the operating system is a kind of destroyer. Otherwise, the rule matching is used to recognize the non-self by the antibody and the rule-base on the adaptive immune tier. The rule includes two parts: the first one is the condition of the non-self feature, and the second one is the conclusion of the rule-based reasoning, which shows the type of the non-self and the elimination approach of the non-self. The rule matching is similar to the combination of DNA genes. And the immune algorithm is built on the random search of the rules. If the random search is done through evolutionary algorithm, then the immune algorithm is built on the evolutionary algorithm (Jiao & Wang, 2000; Deng & Korobka, 2001; Bell, 1970). Cooperative co-evolutionary adaptive genetic algorithm (CCAGA) is suitable for parallel computation, which is convenient to solve complicated problems (Cai & Peng, 2002).

In the immune computing model of the static web immune system, the immune computation has the threshold that is alike in the immune response of many biological immune systems. And the threshold is caused by the long-time cost of the random search. Moreover, the antibody search and rule matching are large-scaled in the chaos state.

A.3.2 Innate Immune Tier

The innate immune tier of the artificial immune system is inspired from the innate immunity of the biological immune system, and this tier is responsible for detecting all the selfs & non-selfs and recognizing the known non-selfs whose features have been stored in the non-self database. The normal model provides a certain representation of selfs and is useful for modeling the static web immune system. The normal model is the information basis of the model for detecting selfs and non-selfs with the space-time properties of the selfs, and the probability for detecting the selfs and the non-selfs can attain 100% in theory.

In the innate immune tier, recognition of foreign objects is relatively simple and quick, because this operation is only based on matching the feature information of the foreign objects and the records of the known non-selfs in the non-self database, and the operation for matching them can be done by the operator for querying. According to the results for querying, the corresponding methods for eliminating the non-selfs may be called from the records, for example some methods is used to delete the files that have been infected by some viruses. In the innate immune tier, there are also the operators for capturing the features of the non-selfs and querying, the non-self database, and so on. If a record of the feature information in the non-self database is matched with the features of the non-self that is being recognized, then the non-self is classified as a known non-self, otherwise it is a unknown non-self.

A.3.3 Adaptive Immune Tier

The adaptive immune tier of the artificial immune system is inspired from the adaptive immunity, and the adaptive immune tier is used to recognize the unknown non-selfs that can not be matched with any record on the feature information in the non-self database. The feature information of all the known non-selfs in the non-self database is represented on the dimension of features in the multi-dimension space, as called the feature space of the non-selfs, and the feature space is used to learn unknown features and types of the unknown non-selfs. By random searching and reasoning in the feature space, the most similar known non-selfs in features are found for the unknown non-selfs. These conclusions are memorized into the non-self database with the operator for memorizing the unknown non-selfs, so that the unknown non-selfs are transformed into new known non-selfs, which shows an immune memory of the artificial immune system. The advantage of such intelligence is to quickly recognize the same type of non-selfs in the innate immune tier as the memorized non-self for the next time and need no recognition in the adaptive immune tier, as the second immune response is much quicker than the first immune response.

The algorithm that is used to recognize the unknown non-selfs is called as artificial antibody, and many parallel antibodies are searching in the feature space.

A.3.4 Parallel Immune Tier

The parallel immune tier is inspired from the parallel immune response of many immune cells in the biological immune system, and parallel immune computation is used to break through the bottleneck of efficiency in the artificial immune system. The parallel immune tier provides a high-performance computing infrastructure for the innate immune tier and the adaptive immune tier, and can be used for solving the problems of limited computing and load balance. The computing capability and resource for one host may be limited for complex immune computation, and computing with overload is unsafe, easy to wither and of high risk. When information that the static web system processes is overload for single processor, the parallel immune tier is called and data are backed up and repaired in multi-threads.

The artificial immune system for the static web system eliminates the non-selfs such as some viruses and abnormity with immune agents and destroyers, but the capability for an immune agent is limited. When a large amount of unknown evil non-selfs attack the static web system, the speed for detecting recognizing and eliminating the non-selfs may be smaller than the speed for the non-selfs to clone transport and attack the system. Therefore, some parts of the artificial immune system may be infected by the non-selfs, and the load for immune computing will be increased. In this way, the speed for immune computing will be smaller and smaller, and then much smaller than the speed for the non-selfs to clone and attack the system. On the other hand, more parts of the artificial immune system will be infected and damaged by the non-selfs and in the end the static web system will be destroyed completely. Moreover, when the artificial immune system is quite abnormal, the immune computation and some destroyers may quicken damage to the static web system.

A.4 SELF/NON-SELF DETECTION OF STATIC WEB IMMUNE SYSTEM

The normal model is a new technique for the artificial immune system, and the model has powerful functions. Therefore, the static web immune system based on the normal model has some new traits, and one of them is the self/non-self detection based on the normal model. Many traditional approaches for detecting abnormity attain low probability for detecting some unknown abnormity, so that many researchers do not believe that there is probability for detecting all the non-selfs in a system. But the normal artificial immune system based on the normal model can detect all the selfs and all the non- selfs in the static web system, in theory.

A.4.1 Self Detection Based on Normal Model

The model for detecting selfs based on the normal model is comprised of the operator for visiting components, the operator for reading the space-time properties, the operator for querying, the static web system and the set of detecting results, shown in Figure 5. First, the operator for visiting components selects a component of the static web system as the object that is being detected in one turn. For the object that has been selected, both the space property and the time property of the object is measured with the operator for reading the space-time properties, and the space-time properties are encapsulated as an immune object. Next, the operator for querying is used to query whether there is any record that matches the immune object. If yes, then the object is determined as a self. Such is repeated until all the components in the static web system are all detected. At last, the results for detecting the selfs are stored into the set of detecting results.

A.4.2 Non-Self Detection Based on Self Detection

The algorithm for detecting the non-selfs is based on the model for detecting the selfs and the recursive logic. For a component that is being detected, the space property and the time property of the component are used to determine whether the component is a self, at first. For a sub-system, the sub-system is checked recursively to detect whether any component of the sub-system is not a self. Suppose the current static web system has l components that are being detected, the algorithm for detecting the non-selfs is show in Figure 6.

A.4.3 Probability for Detecting Selfs and Non-Selfs

According to the unique relationship between the state of the components and the space-time properties of the components, the function can be established between the state set $\{s(c_i)\}$ of the components and the bi-dimension set $\{(p_i, t_i)\}$ of the space-time properties as such.

$$s(c_i) = f((p_i, t_i)) = g(p_i, t_i). \tag{3}$$

Figure 5. Model for detecting selfs based on the normal model. ©2008 Tao Gong. Used with permission.

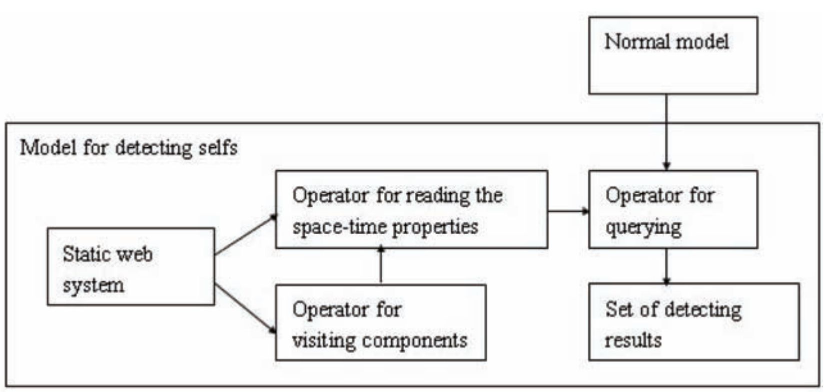


Figure 6. Algorithm for detecting the non-selfs by detecting the selfs. ©2008 Tao Gong. Used with permission.

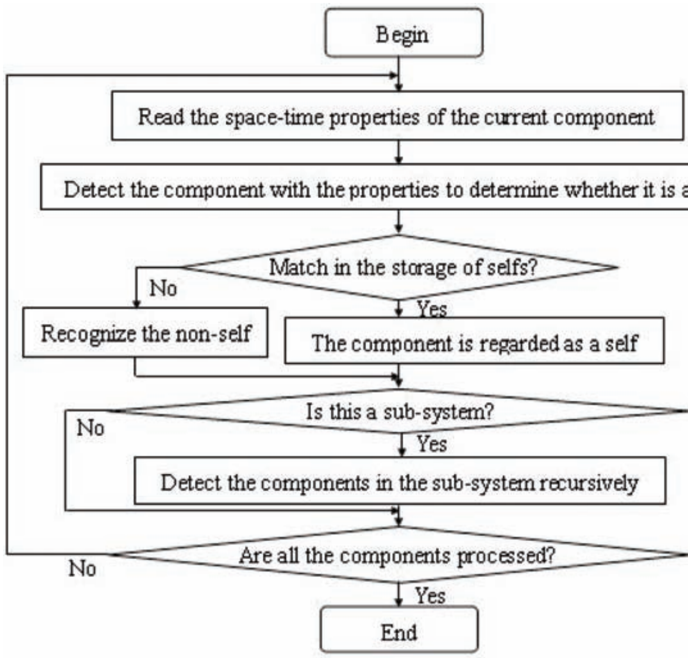


Here, $f(.)$ represents the mapping from the vector (p_i, t_i) to the state $s(c_i)$ and $g(.)$ represents the mapping from the space property p_i and the time property t_i to the state $s(c_i)$.

To investigate how to improve the approach for detecting the non-selfs, some definitions should be given on the probability for detecting the non-selfs.

Definition A.1 Self/non-self detection of the artificial immune system is a random event, and the event is denoted with D. The measurement on the probability of the random event is called as the probability for detecting the selfs and the non-selfs, and the probability is denoted with $P(D)$. Suppose the number of the selfs that have been detected during immunizing is n_s, the number of the non-selfs that have been detected during immunizing is n_n, the sum of selfs before immunizing is s_s, the sum of non-selfs before immunizing is s_n, then the probability $P(D_s)$ for detecting the selfs can be represented as such.

$$P(D_s) = \frac{n_s}{s_s}. \tag{4}$$

The probability $P(D_n)$ for detecting the non-selfs can be represented as such.

$$P(D_n) = \frac{n_n}{s_n}. \tag{5}$$

Theorem A.2 Suppose an artificial immune system detects the non-selfs in the static web system, which the artificial immune system protects, by matching the features of the non-selfs, the feature set of the known non-selfs is denoted with $U=\{u_i, i=1, 2, \ldots, C\}$, and some non-selfs are unknown, then the probability for detecting the non-selfs is smaller than 1, i.e. $P(D_n)$<1, and the probability can not be 100% in theory and real applications.

[Proof] Suppose the feature set of the unknown non-selfs is denoted with I, the probability for detecting the unknown non-selfs by the artificial immune system is $P(D_n)=|U|/|I|=C/|I|$. Because the non-selfs are unknown, the set I can be an unlimited set, and the element number of the set I can be ∞. Moreover, for any limited set U, there is at least one feature r of one unknown non-self that is not included in the set U, so that the artificial immune system can not detect the unknown non-self. Therefore, $P(D_n)$<1. ■

Theorem A.3 Suppose the data of the space-time property set in the storage of selfs are correct, and the operator for detecting the selfs and the non-selfs by the artificial immune system is normal, the probability for detecting the selfs by the artificial immune system based on the normal model of the static web system can be 100% in theory, i.e. $P(D_s)=1$; the probability for detecting the non-selfs can also be 100%, i.e. $P(D_n)=1$.

[Proof] The normal states of all the components in the static web system, which the artificial immune system protects, are uniquely identified with the bi-dimension data of the space properties and the time properties. Thus, when the normal components are being detected with the normal model of the static web system, all the normal components can be matched in the storage of selfs, so that all the normal components can be detected. Therefore, no normal component has been detected as a non-self, and no abnormal object has been detected as a normal component. Hence, all the non-selfs can be detected.

$$P(D_s) = \frac{n_s}{s_s} = \frac{\sum_{i=1}^{n+m} N(s(C_i))}{s_s} = \frac{s_s}{s_s} = 1$$

$$P(D_n) = \frac{n_n}{s_n} = \frac{l - s_s}{s_n} = \frac{s_n}{s_n} = 1$$

In conclusion, with the artificial immune system and the normal model of the static web system, the probability for detecting the selfs can be 100%, and the probability for detecting the non-selfs can also be 100%. ■

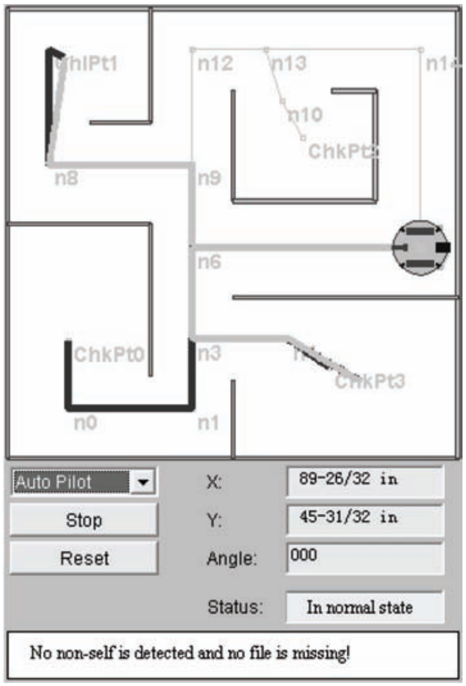
The complete detection of the non-selfs can detect more non-selfs from unknown non-selfs, so that the next step for recognizing the non-selfs will have more non-selfs to learn.

A.4.4 Experiments for Detecting Selfs and Non-Selfs

To test the approach for detecting non-selfs by detecting the selfs with the normal model, a web demo system was infected by some unknown worms and then its immune mechanism was activated. The unknown worms mean that the worms can not be matched in the storage of worms for the artificial immune system, and there are three variants of known worms and two complete-unknown worms among the unknown worms. The three variants are respectively modified from the loveletter worm, the happy-time worm and the Jessica worm (Levy, 2005; Arce & Levy, 2003; Zou, Gong & Towsley, 2002). The worms copy themselves into the file system of the static web system, overwrite the system files and the registration data of the operating system, and spread themselves via the e-mail system. If the static web system is attacked and affected by the worms, the users will feel that the system becomes much slower and more unstable, and the other computers or movable memorizers that connect the static web system may also be affected by the worms.

The experiment was setup on the web demo system of robots, as shown in Figure 7, and the machine was with double CPUs and 2GB memory. First, the selfs of the web demo system were represented with the normal model of the

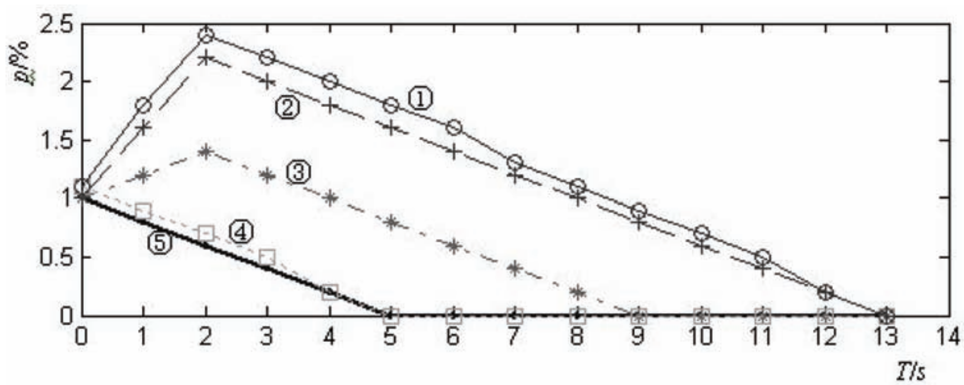
Figure 7. Initial web demo system when the system is normal. ©2008 Tao Gong. Used with permission.



system, and the normal model was uniquely identified by the space-time properties of all the normal components when the initial system was normal. The system was a part of web-based e-learning system, which was developed by some web programming languages such as HTML JSP, Java and JDBC. The system was used to show how a fire-fighting robot searches a path to find the fire and put out the fire, and the initial system was normal. Therefore, at the initial normal state the normal model of the system was built and used to represent the selfs.

To detect and eliminate the worms and the variants in the web demo system, the immune programs were tested in 50 experiments on the machine. The experiments of immune computation show that the non-self percent *p* decreases from the initial value to zero, and the non-self percent may increase first and then decreases due to the spread of the worms, as shown in Figure 8. The time is denoted as *T* and the unit of the time is second. The minimization of the non-self percent means that the elimination of the worms is accomplished and the danger from the worms disappears. The non-self percent means the ratio of the sum of current worms to the sum of components in the current system, and different curves represent different immunization against different worms. The first condition for the first curve is that some files are lost in the Web system; the second condition is that the initial ratio of the sum of worms to the sum of files is 1.1%; and the third condition is that when the artificial immune system detects and eliminates the worms, the worms are activated to copy themselves and produce new worms, until the process of the worm is closed, and then the worms are eliminated. The first condition for the second curve is that no file is lost in the Web system; the second condition is that the initial ratio of the sum of worms to the sum of files is 1%; and the third condition is that when the artificial immune system detects and eliminates the worms, the worms are activated to produce new worms, until the process of the worm is closed, and then the worms are eliminated. The first condition for the third curve is that no file is lost in the Web system; the second condition is that the initial ratio of the sum of worms to the sum of files is 1%; and the third condition is that when the artificial immune system detects and eliminates the worms, the worms are activated to infect some self files, until the process of the worm is closed, and then the worms are eliminated. The first condition for the fourth curve is that some files are lost in the Web system; the second condition is that the initial ratio of the sum of worms to the sum of files is 1.1%; and the third condition is that when the artificial immune system detects and eliminates the worms, the worms are not activated. The first condition for the fifth curve is that no file is lost in the Web system; the second condition is the

Figure 8. Non-self percent of immune computation. ©2008 Tao Gong. Used with permission.



initial ratio of the sum of worms to the sum of files is 1%; and the third condition is that when the artificial immune system detects and eliminates the worms, the worms are not activated.

A.5 RECOGNITION AND LEARNING OF NON-SELFS IN STATIC WEB IMMUNE SYSTEM

For the artificial immune system, the recognition of the non-selfs is classified into two types according to the difference among the non-selfs, and the two approaches for recognizing the non-selfs are inspired from the innate immunity and the adaptive immunity in the biological immune system. The first approach is used to recognize the known non-selfs by matching the features of the known non-selfs in the storage of non-selfs. The second approach is used to recognize some unknown non-selfs by the random search for finding the most similar known non-selfs to the unknown non-selfs in the feature space of the non-selfs and learning the unknown non-selfs.

A.5.1 Recognition of Known Non-Selfs

Before designing the algorithm for recognizing the known non-selfs on the model for recognizing the known non-selfs, the storage of non-selfs must be designed. The storage of non-selfs is used to represent and store the feature information of all the known non-selfs, and the feature information includes the space information of the non-selfs, the feature string of the non-selfs, the copying behavior of the non-selfs, the modifying behavior of the non-selfs to the registration data, the calling behavior of the non-selfs to the e-mails and so on.

The multi- dimension feature information of the non-selfs is encapsulated into the feature objects of the non-selfs, and the feature objects of the non-selfs consist of the set of feature information for the non-selfs. The set of feature information is called as the feature space of the non-selfs, shown in Table 1.

In Table 1, the feature information of the known non-selfs should be input into the storage of non-selfs first, and the software of database management can be used to import the data. For example, for the loveletter worms, if the worms are known for the artificial immune system, then the data of the loveletter worms can be input into the storage of non-selfs. The data include 1) Non-self No.: w00001, 2) Space information of the non-selfs (File-extension): vbs, 3) Feature string of the non-selfs: loveletter, 4) Copying behavior of the non-selfs: .Copy, 5) Modifying behavior of the non-selfs to the registration data: .RegWrite, 6) Calling behavior of the non-selfs

Table 1. Dimension of the feature space for the non-selfs

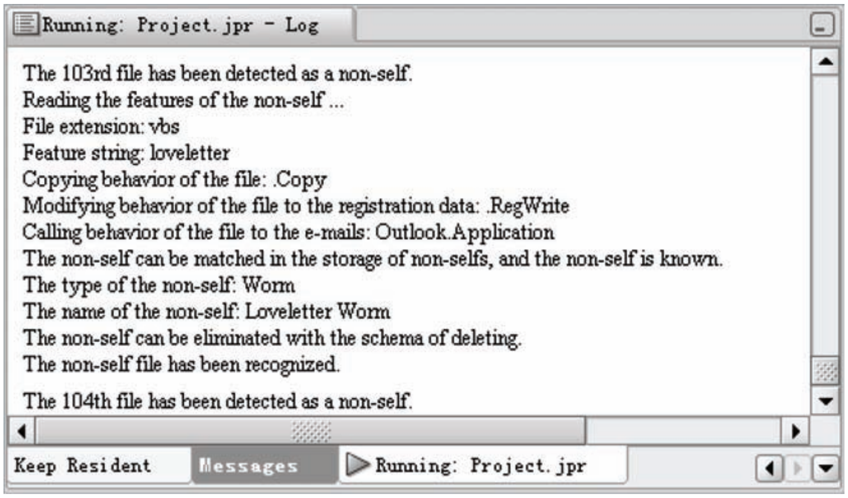
Dimension No.	Dimension of non-selfs' features	Description of non-selfs' features
1	u_1	Non-self No.
2	u_2	Space information of the non-selfs
3	u_3	Feature string of the non-selfs
4	u_4	Copying behavior of the non-selfs
5	u_5	Modifying behavior of the non- selfs to the registration data
6	u_6	Calling behavior of non-selfs to the e-mails
7	u_7	Non-self name
8	u_8	Type of the non-self
9	u_9	Eliminating schema of the non-self
…	…	…

to the e-mails: Outlook.Application, 7) Non-self name: loveletter worm, 8) Type of the non-self: worm, 9) Eliminating schema of the non-self: delete and so on.

At first, the algorithm for recognizing the known non-selfs queries the space information of the non-self in the feature space, which is represented in the storage of non-selfs. If a record is matched with the space feature of the non-self that is being recognized, then other features of the non-self are recognized for the next steps, otherwise the non-self is regarded as an unknown non-self. Afterwards, the feature string, the information on the copying behavior, the information on the modifying behavior to the registration data and the information on the calling behavior to the e-mails are extracted from the non-selfs. If the features of the non-selfs can be matched with any samples in the feature space that has been built with all the known non-selfs, then the non-self is a new sample of known non-selfs.

In the static web demo system, the algorithm for recognizing the known non-selfs reads the file extension of the non-self file at first. If at least one record is matched on the file extension, then the algorithm for recognizing the known non-selfs continues to recognize the other features of the non-self and classifies the non-self into an existing type of the known non-selfs; otherwise, the file is regarded as a unknown non-self, and the algorithm for learning the unknown non-selfs is used to recognize the unknown non-self. After the matching record is found, the information of the record is read according to the feature string, the copying behavior, the modifying behavior to the registration data, and the calling behavior to the e-mails and so on. For example, the loveletter worm has been recorded as a known non-self

Figure 9. Recognition of the known non-selfs by the algorithm. ©2008 Tao Gong. Used with permission.



in the storage of non-selfs, and the No. of the worm is w00001, so the result for recognizing the loveletter worm is shown in Figure 9.

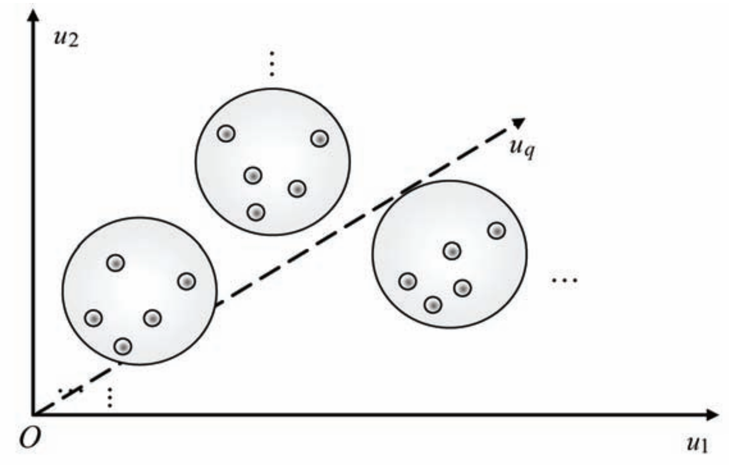
In Figure 9, the file that has been infected by the loveletter worm has been detected as a non-self. Afterwards, the algorithm for recognizing the known non-selfs is used to recognize the file's features such as the file extension, the feature string, the copying behavior of the file, the modifying behavior of the file to the registration data, the calling behavior of the file to the e-mails and so on. By matching the features of the non-self with the records in the storage of non-selfs, the non-self is recognized as a known non-self, and the type of the non-self is worm. The name of the non-self is Loveletter Worm, and the schema of deleting can be used to eliminate the non-self.

A.5.2 Feature Space that is Built with all the Known Non-Selfs

Suppose the feature dimension of all the known non-selfs is q, the feature vector of the non-self c_j among the known non-selfs is denoted with $(u_{j1}, u_{j2}, \ldots, u_{jq})$, the feature space of the non-selfs is represented with $\{(u_{j1}, u_{j2}, \ldots, u_{jq})\}$, shown in Figure 10, j=1, 2, …, M, and M denotes the sum of the known non-selfs. The known non-selfs are classified into many classes, and the number of the classes is limited and numerable at any time. After the process for learning the unknown non-selfs, the unknown non-selfs are classified into the type of the most similar known non-selfs to the unknown ones or given new classes, according to the feature vector of the unknown non-selfs. Sometimes, the unknown non-selfs can not be classified into any type of known non-selfs, and new classes must be created for the unknown ones at that time. With creation of new class repeated, the classes of unknown non-selfs may be unlimited but numerable.

In Figure 10, the dimension coordinate of the feature space for the non-selfs is represented with u_i, i=1, 2, …, q, small balls are used to denote the non-selfs, and the big circles represent the classes of the non-selfs. For the problem for learning unknown non-selfs with unlimited class, current approaches of machine learning are not quite suitable, so that the class of unknown non-selfs is regarded as a limited variable in some applications.

Figure 10. Feature space of non-selfs with unlimited class expending. ©2008 Tao Gong. Used with permission.



A.5.3 Learning of Unknown Non-Selfs

Suppose the current static web system that the artificial immune system protects has l components, among which the algorithm for recognizing known non-selfs has regarded l_2 components as unknown non-selfs. There is some feature information for K known non-selfs in the storage of non-selfs, and each non-self has q features that are coded in some tables. The problem for recognizing the unknown non-selfs can be solved by finding the most similar known non-self to the unknown non-self and/or creating a new class for the unknown non-self, and the problem for finding the most similar known non-self to the unknown non-self is a constrained optimization problem. Suppose the difference between the unknown non-self c_u and the known non-self c_i is represented with the function $f(c_u, c_i)$, the constrained optimization problem is described as such (Cai & Wang, 2006).

minimize $f(c_u, c_i)$ $c_u = (u_{u1}, x_{u2}, \cdots, x_{uq}) \in \Re^q$

$$c_i = (u_{i1}, x_{i2}, \cdots, x_{iq}) \in \Re^q$$

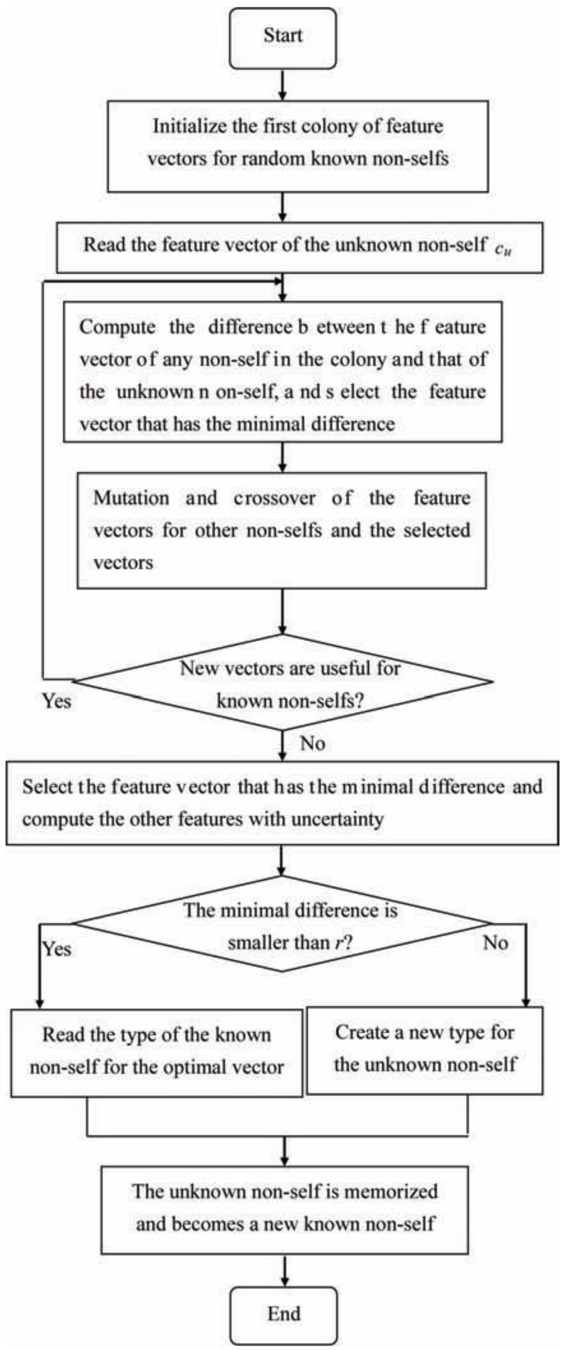
subject to: $f(c_u, c_i) < r$ (6)

Here, r represents the threshold that is used to determine if the unknown worm belongs to any class of known non-selfs.

The constrained optimization problem for finding the most similar known non-self to the unknown non-self can be solved with some evolutionary algorithms, and the algorithm for recognizing the unknown non-selfs is designed with immune memory, shown in Figure 11. The immune memory means that the unknown non-self can be transformed into a known one after learning, and the immune learning is enhanced.

- **Step 1.** Select some known non-selfs with random probability from the storage of known non-selfs, and build the first colony for evolutionary computation with the feature vectors of the selected non-selfs.
- **Step 2.** Read the measurable features of unknown non-self c_u, and build its feature vector.
- **Step 3.** Compute the distance between the feature vectors of the unknown non-self

Figure 11. Algorithm for recognizing the unknown non-selfs with immune memory. ©2008 Tao Gong. Used with permission.



c_u and each known non-self in the colony, and sort the distances that represent the difference between the unknown non-self and the known non-selfs. Select the minimal distance and keep the relevant feature vector and known non-self.

- **Step 4.** Mutate and cross in the colony of feature vectors with the feature vectors of other known non-selfs and the feature vector of the unknown non-self.
- **Step 5.** Match the new vector with the feature vectors of all the known non-selfs. If the new vector belongs to any other known non-self, call step 3 to continue the random search; otherwise end the loop, and select the feature vector that has the minimal distance. Then compute unknown features of the unknown non-self with the feature vector that has the minimal distance.
- **Step 6.** Determine whether the minimal distance is smaller than *r*. If yes, then the unknown non-self belongs to the type of the known non-self whose feature vector has the minimal distance; otherwise, the unknown non-self is regarded as a new class of non-selfs and a new class is created for the unknown non-self.
- **Step 7.** Memorize the feature vector of the unknown non-self, and then the unknown non-self becomes a new known non-self.

A.5.4 Probability for Learning Non-Selfs

Before the algorithm for recognizing the unknown worms is used, the unknown worms must be detected. The algorithm for detecting selfs and non-selfs on the normal model is used to detect whether the object is a self or non-self, and the algorithm for recognizing the known non-selfs is used to determine whether the non-self is a known non-self or unknown non-self. For recognizing more unknown non-selfs the stage for detecting selfs and non-selfs is very crucial, and the stage for recognizing known non-selfs is relatively simple.

With the space properties and the time properties of the components, the normal model uniquely identifies the normal state of each component and the normal state of the whole static web system that the artificial immune system protects. Therefore, based on Theorem A.3, the following theorem shows the advantages of the normal model to the algorithm for recognizing the unknown non-selfs.

Theorem A.4 Suppose the event that the artificial immune system detects the non-selfs by matching the features of the non-selfs is denoted with D_T, the event that the artificial immune system detects the non-selfs is denoted with D_N, the probability for recognizing the unknown non-selfs based on the normal model is represented with $P(R|D_N)$, the probability for recognizing the unknown non-selfs only based on matching the features of the non-selfs is represented with $P(R|D_T)$, then $P(R|D_N)>P(R|D_T)$.

[Proof] The artificial immune system recognizes the unknown non-selfs after the system detects some non-selfs as the unknown non-selfs. Thus, the probability for recognizing the unknown non-selfs is a conditional probability $P(R|D)$, which is the probability of the event that unknown non-selfs are recognized on the condition that the non-selfs are detected.

$$\because P(D_N) = 1,\ P(D_T) < 1,$$
$$\therefore P(D_N) > P(D_T)$$
$$\therefore P(R \mid D_N) = P(R) > P(R \mid D_T)$$
■

A.5.5 Experiments for Learning Non-Selfs

After the experiment for detecting selfs and non-selfs were done, the experiment for learning non-selfs was activated. The algorithm for detecting selfs and non-selfs on the normal model was used to detect whether the object is a self or non-self, and the algorithm for recognizing the known non-selfs was used to determine whether the non-self is a known non-self or unknown non-self.

In the web demo system shown in Figure 7, 50 independent trials for learning the non-selfs are executed with MATLAB offline. In the algorithm for learning unknown worms with evolutionary computation, the common recombination operator involve simulated binary crossover (SBX), simplex crossover (SPX) (Tsutsui, Yamamure & Higuchi, 1999) etc. In this test, the algorithm adopts SPX, which generates offspring based on uniform probability distribution and does not need any fitness information, as the recombination operator. In $\Re^n$, μ mutually independent parent vectors $(\vec{x_i}, i = 1, \cdots, \mu)$ form a simplex, and Figure 12 illustrates the density of the offspring produced with three-parent SPX.

The production of an offspring consists in: 1) employing a certain ratio to expand the original simplex in each direction $\vec{x_i} - \vec{o}$ ($\vec{o}$ is the center of μ vectors, $\vec{o} = (1) / (n+1) \sum_{i=1}^{\mu} \vec{x_i}$) and forming a new simplex; and 2) choosing one point form the new simplex as an offspring.

The evolutionary search was tested with some benchmark functions such as g1, g2, g3, g10,

g11	0.750	0.750000	0.750000	0.750000	1.546E-12	0.750000	56
g12	-1.000000	-1.000000	-1.000000	-1.000000	0.000E+00	-1.000000	100

g11, g12 (Cai & Wang, 2006), and the evolutionary algorithm in the static web immune system showed good optimum and performance, shown in Table 2. For example, when the benchmark function g10 was tested with 100 experiments, the convergence curves of the two experiments among them are shown in Figure 13. At first, the evolutionary search with some constraints jumped up and down beside the optimum and then found much closer solutions to the optimum than before until the convergence of the algorithm was accomplished.

The immune memory is a kind of rote learning, and the memory part can be regarded as a function $m(\cdot)$ in mathematics. The input vector of the memory function is $(u_{j_{i_1}}, u_{j_{i_2}}, \cdots, u_{j_{i_o}})$, and the output vector of the memory function is the combination of unknown features and unknown type of the unknown worm, as denoted with $(u_{j_{l_1}}, u_{j_{l_2}}, \cdots, u_{j_{l_{q-o}}}, T)$. The immune memory can be searched directly and easily, and no repeated immune computation is needed for learning unknown features and type, when the memory function $m(u_{j_{i_1}}, u_{j_{i_2}}, \cdots, u_{j_{i_o}})$ is called (Cai & Xu, 2004).

$$(u_{j_{i_1}},\cdots,u_{j_{i_o}}) \xrightarrow{m} (u_{j_{l_1}},\cdots,u_{j_{l_{q-o}}},T) \xrightarrow{\text{storing}} ((u_{j_{i_1}},\cdots,u_{j_{i_o}}),(u_{j_{l_1}},\cdots,u_{j_{l_{q-o}}},T)) \quad (7)$$

In this example, the three variants v_1, v_2, v_3 are recognized to belong to three classes of the loveletter worms, the happy-time worms, and the Jessica worms respectively, and the three

Figure 13. Convergence of the two evolutionary searching curves. ©2008 Tao Gong. Used with permission.

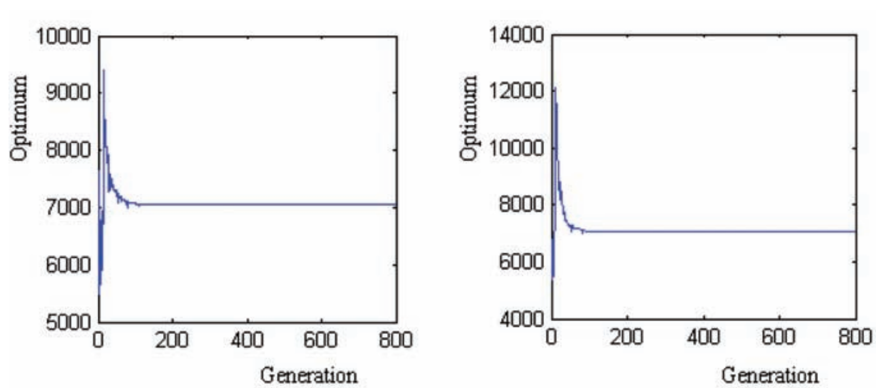

Figure 14. Learning results of the unknown worms in the feature space. ©2008 Tao Gong. Used with permission.

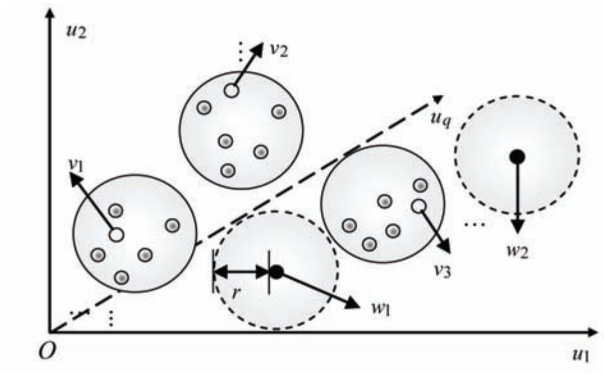


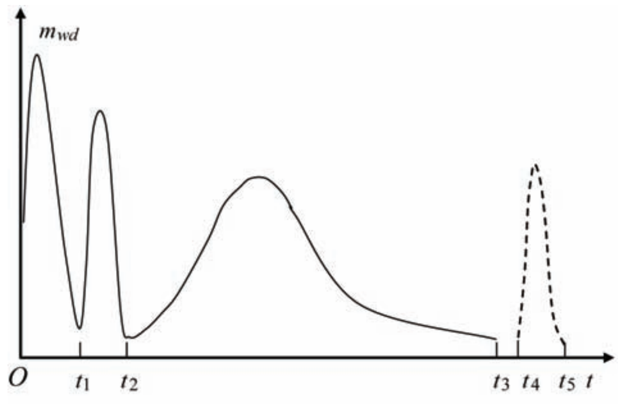
classes are known, shown as the real-line circle in Figure 14. The other unknown worms w_1, w_2 are recognized as two brand-new unknown worms, and two new classes are created for them, shown as the dashed circle.

The web demo system is immunized by the artificial immune system and is now immune from some worms. When many known worms and the unknown worms attack the demo system that the artificial immune system protects, the innate immune tier is activated to detect the worms and recognized the known worms. Detection of all the worms and recognition of the unknown worms are both quick because of the normal model and the storage of known worms, shown as the curve from the time point 0 to t_2 in Figure 15. After the innate immune tier confirms that the unknown worms are not any known worms, the adaptive immune tier begins to learn the unknown worms with random evolutionary search, shown as the curve from the time point t_2 to t_3 in Figure 15, and the most similar known worm is found to decide whether the unknown worms belong to any type of known worms or are really new type of worms. The learning results are memorized so that the unknown worms are transformed into new known worms in the end. If another variant of the loveletter worm attacks the demo system, the artificial immune system recognizes the variant as a known worm now and the immune response is quick from the time point t_4 to t_5 in Figure 15. Here, m_{wd} represents the sum of the worms that have been processed, and t represents the time coordinate.

In Figure 15, the primary immune response includes the self/non-self detection and recognition of the known worms, and the detection is accomplished from the time point 0 to t_1. The secondary immune response is from the time point t_2 to t_3, which is much longer than the primary immune response. In fact, the hypothetic immune response from the time point t_4 to t_5 is a part of the primary immune response after the secondary immune response.

The experiments are made on the web-based course system, and the web demo system is a part. Over a hundred of worms attack the web system, and many files are infected. The artificial immune system detects all the worms successfully with the normal model and the approach for detecting selfs and non-selfs. But only with some intelligent techniques such as the artificial neural network, the probability for detecting the non-selfs is smaller, and such result affects the process of recognizing

Figure 15. Immune response to the known worms and the unknown worms. ©2008 Tao Gong. Used with permission.



the worms. With the immune learning algorithm after detecting the worms with the normal model, the artificial immune system recognizes the unknown worms with the higher probability than the result with the artificial neural network with the BP algorithm.

A.6 CONCLUSION

The tri-tier immune computing model is a useful and effective model for the static Web immune system. The first tier is the innate immune computing tier, the second tier is the adaptive immune computing tier, and the last tier is the parallel immune computing tier.

The theorems prove that, on the condition that the time property is correct, the normal model and the tri-tier immune computing model are useful for increasing the probability of detecting selfs and non-selfs in the static web system. Many anti-worm experiments of immunization validate effectiveness and advantages of the static web immune system and the immune algorithms. The static web immune system can eliminate worms and repair itself with higher probability for detecting non-selfs than traditional approaches.

A.7 FUTURE DIRECTIONS

This work emphasized on static web immune system, and this is new try of new techniques for immune computing. But this is just a beginning, the next work is emphasizing and will emphasize on dynamic web immune system. The related issues abut the dynamic web immune system can be shown in the following:

1) Normal model of dynamic web immune system. How to build the normal model for the dynamic web immune system and how to transform the normal model from a normal state to another normal state are the difficult bottlenecks for representing the selfs.
2) Adaptive learning of unknown non-selfs. If the viruses are designed by the most intelligent programmers, how to design the adaptive learning mechanism of complete-unknown non-selfs is really a difficult problem for other most intelligent programmers.
3) Design of artificial immune system for the operating systems. It is very difficult to build a normal model for a Windows operating system, because the designers for the Windows operating system do not really know when the system is normal or abnormal.

KEY TERMS AND DEFINITIONS

Adaptive Immune Tier: The immune computing tier, which learn and recognize the unknown non-selfs, is called as the adaptive immune tier of the artificial immune system.

Immune Memorization: The process for remembering the unknown non-selfs to transform the non-self into the known ones is called as the immune memorization.

Innate Immune Tier: The immune computing tier, which detects the selfs & non-selfs and recognize all the known non-selfs, is called as the innate immune tier of the artificial immue system.

Non-Self Database: The database that stores the feature information of the known non-selfs is called as the non-self database.

Normal Model of Normal Static Web System: The set of space-time properties for all the normal components of the normal static web system is called as the normal model of the normal static web system.

Parallel Immune Tier: The immune computing tier, which uses parallel computing to increase efficiency and load balance of immune computation, is called as the parallel immune tier of the artificial immune system.

Probability for Detecting Non-Selfs: The measurement on the probability of the random event that the artificial immune system detects the non-selfs is called as the probability for detecting the non-selfs.

Probability for Learning Unknown Non-Selfs: The measurement on the probability of the random event that the artificial immune system learns the unknown non-selfs is called as the probability for learning the unknown non-selfs.

Self Database: The database that stores the space-time information of the selfs is called as the self database.

Self/Non-Self Detection: The process for detecting the object to decide whether the object is a self or non-self is called as the self/non-self detection.

Chapter 7.18
Mapping Policies to Web Rules: A Case of the KAoS Policy Language

Nima Kaviani

ABSTRACT

Web rule languages have recently emerged to enable different parties with different business rules and policy languages to exchange their rules and policies. Describing the concepts of a domain through using vocabularies is another feature supported by Web rule languages. Combination of these two properties makes web rule languages appropriate mediums to make a hybrid representation of both context and rules of a policy-aware system. On the other hand, policies in the domain of autonomous computing are enablers to dynamically regulate the behaviour of a system without any need to interfere with the internal code of the system. Knowing that policies are also defined through rules and facts, Web rules and policy languages come to a point of agreement, where policies can be defined through using web rules. This chapter focuses on analyzing some of the most known policy languages (especially, KAoS policy language) and describes the mappings from the concepts for KAoS policy language to those of REWERSE Rule Markup Language (R2ML), one of the two proposals to Web rule languages.

DOI: 10.4018/978-1-60566-402-6.ch024

INTRODUCTION AND MOTIVATION

Rules are among the most frequently used knowledge representation techniques. They can generally be categorized as *reaction rules* (event-condition-actions), *integrity rules* (rules of consistency checking), *derivation rules* (implicitly, derived rules), and *production rules* (Boley, Tabet, & Wagner, 2001).

Facts can also be regarded as derivation rules with no premises.

Recently, rule markup languages have started to be considered as the vehicle for using rules on the Web and in other distributed systems, forming a new category of rule languages, referred to as Web rule languages (Wagner, Giurca, & Lukichev, 2006). The main strength of markup languages is their machine readability combined with their inherent potentials to easily be linked to distributed knowledge sources also represented in the form of markup languages (e.g., Data Type Definition (DTD), XML Schema (Fallside & Walmsley, 2004), Resource Description Framework (RDF) (Lassila & Swick, 1999), and Web Ontology Language (OWL) (Smith, Welty, & McGuinness, 2004)). Rule markup languages allow for the reuse, interchange, and publication of rules as well as their communication and execution in a distributed environment. More specifically, rule markup languages allow for specifying business rules as modular, standalone, units in a declarative way, and publishing and interchanging them between different systems and tools (Wagner, Giurca, & Lukichev, 2006). Rule markup languages play an important role in facilitating business-to-customer (B2C) and business-to-business (B2B) interactions over the Internet by enabling information exchange across various stakeholders. For example, they may be used to express derivation rules for enriching Web ontologies by adding definitions of derived concepts, or for defining data access permissions; to describe and publish the reactive behaviour of a system in the form of reaction rules; and to provide a complete XML-based specification of a software agent (Wagner, Giurca, & Lukichev, 2005).

RuleML and *REWERSE Rule Markup Language (R2ML)* are two newly and rapidly emerging Web rule languages that help with interchanging various types of rules from one rule domain to another. RuleML represents an initiative for creating a general rule markup language that will support different types of rules and different semantics (Boley, Tabet, & Wagner, 2001). R2ML more or less follows a similar idea to RuleML; however, its design follows Model Driven Architecture (MDA) defined by the Object Management Group (OMG) (Miller & Mukerji, 2003). Moreover, R2ML is a trial to cover a more comprehensive set of atoms and elements required to develop and define rules, thus bringing more flexibility to rule definition. These rule languages are designed to be conformant and compatible with the guidelines and use cases defined by the Rule Interchange Format (RIF) working group (Ginsberg, Hirtle, McCabe, & Patranjan, 2006).

Policies in the domain of autonomous computing are guiding plans that restrict the behaviour of autonomous agents in accessing the resources (Toninelli, Bradshaw, Kagal, & Montanari, 2005). The main advantage in using policies is the possibility to dynamically change the behaviour of the system by adjusting the policies without interfering with the internal code of the system. They can authorize/oblige the users to, or prohibit/dispense them from, accessing the resources or taking particular actions in the system. Policy languages can be considered as instructional sets that enable phrasing and putting systematic guidelines in place for a target agent. KAoS (Uszok, et al., 2003) is one of the most known policy languages that goes beyond the traditional policy systems by giving special care to the context to which the policies are applied. This is done by enabling these policy languages to use domain knowledge (a.k.a, vocabularies) readily available on the Internet and represented in knowledge representation markup languages such as XML-Schemas, RDF, and OWL.

Knowing that policies are also defined through the use of rules and facts that can share online knowledge bases, Web rules and policy languages come to a point of agreement. Web rules and policies get even closer bringing it into the consideration that most of the newly emerging policy languages also have chosen markup syntax for their specifications (e.g., KAoS). Following the hierarchy of rules represented earlier, a policy rule can be considered a reaction rule which generates an action (possibly permission or denial) upon the occurrence of an event and satisfaction of a series of conditions. On the other hand, a policy rule can be considered a derivation rule that leads to generating additional facts once a set of conditions are satisfied (e.g., a policy may result in concluding that a resource is no longer in use, thus adding an extra fact to the knowledge base). Further to this, a policy rule might be defined in the form of an integrity rule to preserve the integrity of information in a system. All this brings Web rules and policies to a joint end where Web rules can be used to describe policies. The inherent flexibility of Web rule languages in using various vocabularies overcomes the intricate problem of reusing policies across various domains. What is more interesting is that the recent policy languages (including KAoS) can be defined over domain knowledge represented in markup languages such as OWL (Smith, Welty, & McGuinness, 2004) and XML Schema (Fallside & Walmsley, 2004), making it a lot easier to integrate them with Web rules. Furthermore, Web rules have been designed to be compatible with different subsets of first order logic (FOL), ranging from description logic to rule-based logic programs. Consequently, the essence and the semantics of the policy rules specified in different policy languages can be captured agnostic to the logical domain in which the language is grounded. This in turn brings more flexibility and compatibility to Web services to be combined with policies defined in the form of Web rules. There are various benefits in providing bidirectional transformations between policies and Web rule languages. First and foremost, it enables sharing of policies between various business processes which in turn helps with policy reuse from a business system to another. Sharing policies across various business processes is another step towards facilitating B2B and B2C interactions, as discussed above. Additionally, the possibility of converting policies from one language to another, while preserving the semantics of the policies, facilitates the deployments of policies in a business system regardless of the underlying technologies used by its business processes.

In order to be able to decide how a markup policy language can best be described through using a Web rule language, there needs to be a deep analysis of the constructs and elements of one domain to be matched with the corresponding elements in the other domain. This chapter focuses on discussing the building blocks of defining policies (from their logics to their concepts) using markup policy languages, and to find the appropriate matches in a corresponding Web rule language. For the policy languages we will mainly focus on KAoS while for the Web rule we will narrow our focus down to R2ML. This will later on lead us to discuss the possibilities for using a unified modeling language to define and interchanging policies between different policy domains, or even more, to rely on a modeling language to facilitate the definition, design, and integration of policies with other parts of a system, including but not limited to business processes.

This chapter is organized as follows. In Section 2 we will provide some background information on different types of underlying logic for defining policies and rules, some of the most known policy languages, the idea behind rule interchange format, and also a background on Web rule languages. Section 3 discusses our policy interchange framework. In Section 4 we present the metamodels for R2ML and KAoS to discuss high level exchange of concepts between the elements of these languages along with the graphical QVT transformations from each language to the other one and back. Section 5 shows a real example of applying the QVT transformations to the concrete representation of a KAoS policy rule which is then followed by a discussion and conclusion to our findings in Section 6.

BACKGROUND

Before going into the details of how policy languages can be converted to Web rule languages and transformed from one business domain to another, in this section we provide brief background information on the existing policy and Web rule languages. We also discuss how following the principle of modeling can facilitate the process of defining and transforming policy rules from one policy language to another.

Rule Interchange Format

Most of the proposals on Web rule languages are trying to address the use cases and requirements defined by Rule Interchange Format Working Group (Ginsberg, Hirtle, McCabe, & Patranjan, 2006). *Rule Interchange Format (RIF)* (Ginsberg, Hirtle, McCabe, & Patranjan, 2006) is an initiative to address the problem of interoperability between existing rule-based technologies. RIF is desired to play as an intermediary language between various rule languages and not as a semantic foundation for the purpose of reasoning on the Web. It aims to be a widely adopted W3C consistent standard for exchanging rules among different stakeholders. RIF Working Group has defined 10 use cases which have to be covered by a language compliant to the RIF's properties, three of which are dealing with policies and business rules, namely: *Collaborative Policy Development for Dynamic Spectrum Access*, *Access to Business Rules of Supply Chain Partners*, and *Managing Inter-Organizational Business Policies and Practices*. *SWRL* (Horrocks, Patel-Schneider, Boley, Tabet, Grosof, & Dean, 2004) and *RuleML* (Boley, Tabet, & Wagner, 2001) are two of the ongoing efforts in this area trying to serve as rule languages to publish and share rule bases on the Web.

Web Rule Languages

Web rule languages are being developed following the RIF Request for Proposal (RFP) for designing a Web rule language that in the first place provides an intermediary language for exchanging rules between various stakeholders and business processes. The current Web rule languages are not trying to facilitate reasoning on the Web and as a result there is no reasoning engine or infrastructure developed for them. On the other hand, the idea is to have sound transformations from a source rule language to a target rule language, such that the reasoner at the destination (which is of course conformant to the rule language at the destination) can successfully reason over the transformed rules and derive the same conclusions as of the ones at the source. RuleML (Boley, Tabet, & Wagner, 2001) and R2ML (Wagner, Giurca, & Lukichev, 2005) are two of the most known Web rule languages. In this chapter, our focus is more on R2ML, but we briefly skim over RuleML before describing the architecture and of R2ML.

RuleML represents an initiative for creating a general rule markup language that will support different types of rules and different semantics (Boley, Tabet, & Wagner, 2001). It is conceptualized to capture the hierarchy of rule types as we discussed earlier. However, the current version of RuleML covers only some limited forms of rules (Wagner, Damasio, & Antoniou, 2005).

RuleML is built on top of logic programming paradigm of first order logic (i.e. predicate logic). In the tradition of logic programming which is also followed by RuleML, research is focused on computable interpretations of predicate logic, by exploring a great number of semantic extensions and variations. OWL (as well as SWRL (Horrocks, Patel-Schneider, Boley, Tabet, Grosof, & Dean, 2004)) stems from logic-based tradition

Figure 1. An example of a RuleML rule showing the "hasUncle" relationship

    </Atom>
  </body>
</Implies>
```

of artificial intelligence where research is based on classical predicate logic (two-valued) as the one and the only logic. An example of a RuleML rule that uses certain person's attributes to define a rule of "hasMother" and "hasBrother" implies "hasUncle" is shown in Figure 1.

In the next subsection, we skim over the second key web rule language proposal for RIF, known as REWERSE Rule Markup Language (R2ML).

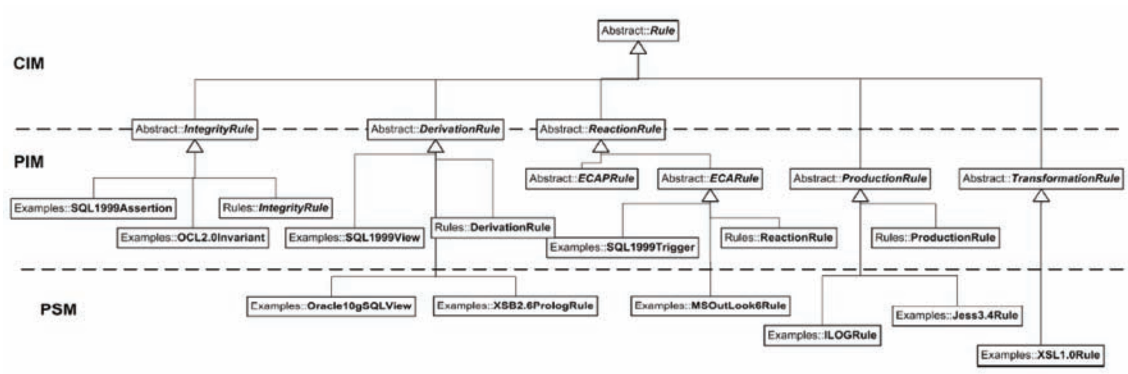
REWERSE Rule Markup Language (R2ML)

R2ML is part of the EU-funded REWERSE project, which follows the goal of providing a general rule markup language to make the deployment, execution, publishing, and communication of rules on the Web possible. The approach chosen to develop the R2ML is based on the known Model Driven Architecture (MDA) (Miller & Mukerji, 2003) and Meta Object Facility (MOF) (ODM, 2001) defined by the Object Management Group (OMG). This means that the whole language definition of R2ML can be represented by using UML diagrams as MOF uses UML's graphical notation. The language also has an XML concrete syntax defined by an XML schema.

As shown in Figure 2, R2ML considers three levels of abstraction for rules. At the *computation-independent business domain* level (called CIM in OMG's MDA), rules are statements that express (certain parts of) a business/domain policy (e.g., defining terms of the domain language or defining/constraining domain operations) in a declarative manner, typically using a natural or visual language. At the *platform-independent operational design* level (called PIM in OMG's MDA), rules are formal statements, expressed in some formalism or computational paradigm, which can be directly mapped to executable statements of a software system. At the platform-specific implementation level (called PSM in the OMG's MDA), rules are statements in a language of a specific execution environment such as XSB Prolog (XSB, 2007).

R2ML provides a vocabulary that enables users to define their own world in the form of objects and elements available in the domain of discourse.

Figure 2. Different abstraction levels considered for rules in R2ML



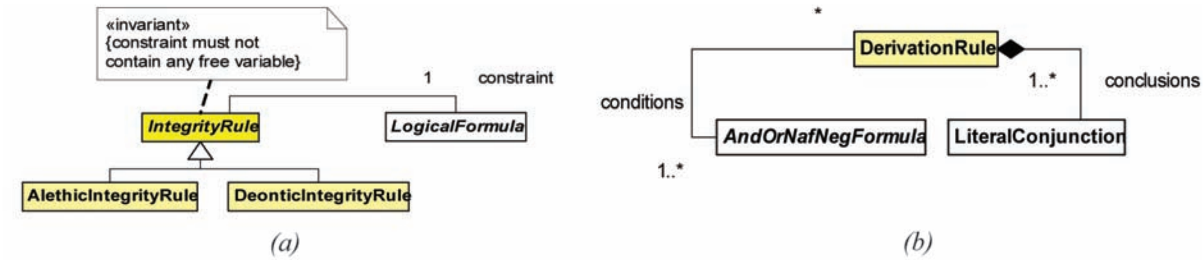
The vocabulary can be defined as a combination of *Basic Content Vocabulary*, *Relational Content Vocabulary*, and *Functional Content Vocabulary.* Basic Content Vocabulary allows the user to specify the basic elements of the domain such as individual objects and data values, classes and data types, and object and data variables. Relational Content Vocabulary helps to associate different objects from different classes through defining n-ary association and association classes. Finally, Functional Content Vocabulary assists with defining functors that correspond to the standard logic of functions. The functions can be data operations to manipulate data values, they can be object operation functions that define object-value operations, or they can be role functions which correspond to functional association (binary association) of the class elements. In (Bradshaw, Dutfield, Benoit, & Woolley, 1997), authors showed how the basic constructs and elements of the OWL language can be transferred and modeled by R2ML atoms and elements. For example, *sameAs* in OWL is equivalent to an *EqualityAtom* in R2ML and *oneOf* in OWL carries the same meaning as *Disjunction* of a set of atoms in R2ML. This means any language with its concepts defined based on OWL (including KAoS and Rei) can be modeled with R2ML constructs elaborately.

Having the objects and concepts of a domain defined, R2ML makes the definition and harmonization of rules over these concepts possible through the use of four different types of rules: *Integrity Rules*, *Derivation Rules*, *Reaction Rules*, and *Production Rules*. Since in this paper we are limited in space, we only review the first two rules and more information about the other rules and constructs of the language can be found in (Wagner, Giurca, & Lukichev, R2ML: A General Approach for Marking-up Rules, 2005).

R2ML integrity rules, also known as (integrity) constraints, consist of a constraint assertion, which is a sentence in a logical language such as first-order predicate logic or OCL (see Figure 3a). R2ML supports two kinds of integrity rules: the *alethic* and the *deontic* ones. The alethic integrity rule can be expressed by a phrase, such as *"it is necessarily the case that"* and the deontic one can be expressed by phrases, such as *"it is obligatory that"* or *"it should be the case that"*. A LogicalStatement is a LogicalFormula that has no free variables, i.e., all the variables from this formula are quantified. In terms of policy languages, integrity rules can be considered as constraints that must hold consistently especially in the level of rule enforcement, e.g. *"it is necessary to give a higher priority to the commands of the administrator than to the commands of the regular users on a system."*

An R2ML derivation rule has conditions and a conclusion (see Figure 3b) with the ordinary mean-

Figure 3. The metamodel for (a) the integrity rule, and (b) the derivation rule in R2ML



ing that the conclusion can be derived whenever the conditions hold. While the conditions of a derivation rule are instances of the *AndOrNafNegFormula* class, representing quantifier-free logical formulas with conjunction, disjunction and negation; conclusions are restricted to quantifier-free disjunctive normal forms without *NAF* (Negation as Failure, i.e. weak negation). In the context of policies, we consider each deontic policy rule as a single derivation rule with the constraints making the conditions of the derivation rule and the policy decision forming the conclusion of the rule, e.g. *"If the user is from Simon Fraser University with a valid student ID then give her the permission to enter the area of the university."* It may sound more expressive to define deontic policy rules with deontic integrity rules in R2ML. However, our attempts in doing so showed that deontic rules in the context of policies carry a different meaning from their interpretation in R2ML. In R2ML, a deontic integrity rule represents a constraint that should be satisfied or must hold with a concrete proof for its truthfulness, though a doentic policy demonstrates concerns over performing a duty or obligation as a result of satisfying a series of related conditions.

Atoms are the basic logical constituents of a rule which are compatible with the concepts of OWL, RuleML, and SWRL. Atoms connect objects to values, classes to instances, and objects to objects, put restrictions on the objects and data values, and so on. Here, we briefly represent some of the atoms that are relevant to our purpose of representing policy languages. *ReferencePropertyAtoms* (see Figure 4) associate object terms as subjects with other terms (objects or data values) as objects. A *ReferencePropertyAtom* in R2ML corresponds to an OWL (and similarly a KAoS) object property, or to the OWL concept of value for an individual-valued property. *ObjectDescriptionAtoms* (see Figure 5) are another class of useful atoms for our purpose. They refer to a class as a base type and to zero or more classes as categories, and consist of a number of property/term pairs (i.e., attribute data term pairs and reference property object term pairs). Any instance of

Figure 4. R2ML's ReferencePropertyAtom

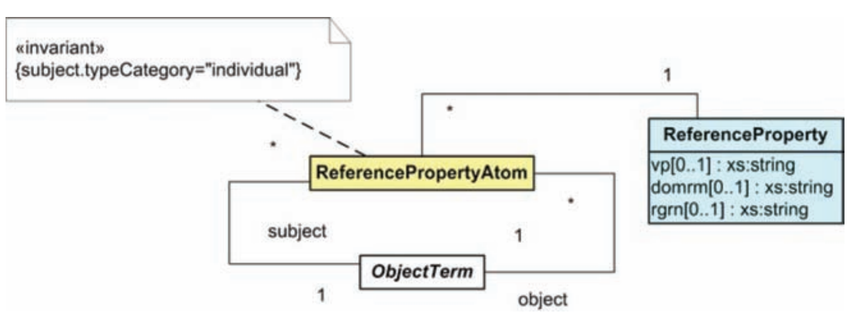


Figure 5. R2ML's ObjectDescriptionAtom

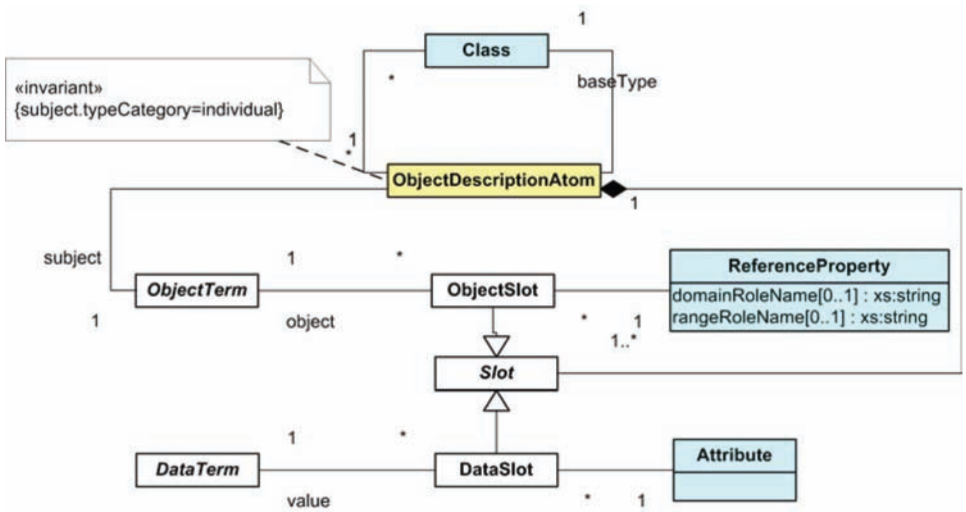


such atom refers to one particular object that is referenced by an *objectID*, if it is not anonymous. This atom corresponds to the instantiation of an object from a class in OWL.

Policy Languages

Policies can be considered as building blocks in enhancing the security, privacy, and usability of a system (Bonatti, et al., 2006). For policies to work effectively, they require to be defined over the domain knowledge that is provided by the domain experts. The process of representing the domain knowledge and defining policy rules over this knowledge, in a machine readable form, is handled by using policy languages. A policy language enables combination of constraints and capabilities, implying rules, over resources that represent policies.

Thus far, there have been various designed policy languages (such as XACML (Godik & Moses, 2003), Ponder (Damianou, Dulay, Lupu, & Sloman, 2001), Protune (Bonatti & Olmedilla, 2005), PeerTrust (Nejdl, Olmedilla, & Winslett, 2004), KAoS (Uszok, et al., 2003), and Rei (Kagal, 2002)) aiming to enable policy engineers to represent their organizational policies in a machine understandable format. In this chapter, we focus on KAoS policy language mainly because *i) it follows a markup format for defining policies*, and *ii) it uses ontologies to represent the domain knowledge*. The first property helps with easier mapping of policies from the KAoS policy languages to a Web rule language, because the source and the target language more or less follow a similar syntactical format. The second property helps with easier transformation of the domain knowledge from the source language to the target language. There have been already efforts on providing accurate mappings between two domain ontologies (Kalfoglou & Schorlemmer, 2003). Such efforts assist with the conversion of the domain knowledge from one conceptual model to a different conceptual model, thus making the domain knowledge easy to be shared across various policy languages and their corresponding reasoning engines.

Rei (Kagal, 2002) and KAoS (Uszok, et al., 2003) are two semantically enriched Web policy languages that use Semantic Web ontologies to define the resources, the behavior, and the users of a domain. Using ontologies enables these two languages to easily adjust themselves to the target system regardless of the number of resources and users in act. KAoS describes the entities and concepts of its world using OWL, while Rei can understand and reason over a domain of concepts defined in either RDF or OWL.

In terms of available policy rules, both KAoS and Rei have four main types. *Permission*, *Prohibition*, *Obligation*, and *Dispensation* in Rei are respectively equivalent to *PosAuthorizationPolicy*, *NegAuthorizationPolicy*, *PosObligationPolicy*, and *NegObligationPolicy* in KAoS. The defined policy rules in each of the languages are then sent to a reasoner that performs the process of conflict resolution and decision making for the rules that match the current state of the world. This task is done by using Stanford's Java Theorem Prover (JTP) in KAoS and a Prolog engine in Rei version 1.0. Rei version 2.0 has extended its reasoning engine to use F-OWL, an ontology inference engine for OWL, based on Flora and XSB Prolog (XSB, 2007). Although these two policy languages have a lot in common there are dissimilarities between them as well. The main difference between KAoS and Rei is the underlying formalism of the languages. KAoS follows description logic coded in the form of OWL expressions with additional constraints that help with defining policy elements and rules. On the other hand, Rei uses its own language that defines policy rules in terms of Prolog predicates expressed as RDF triples. This way Rei follows semantics close to Prolog's semantics which is itself built on top of the concepts of logic programs.

The process of rule enforcement in KAoS is done by extending its enforcement engine depending on the domain it is going to be used in. In Rei, however, there is no rule enforcement engine. Yet, due to the deterministic properties of declarative logic, reasoning over dynamically determined values in Rei policies is more accurate than KAoS in which chances of dealing with unknown situations are likely to happen. In order for processes and services to communicate remotely, Rei relies on a rich set of Speech Acts. In Rei, Speech Acts are used by a sender to express the request for performing one of the actions: *Delegation*, *Revocation*, *Request*, *Cancel*, *Command*, and *Promise* by the receiver. Conversely, in KAoS the remote communication procedure is done through the message passing of the underlying platform.

Defining KAoS policies as OWL expressions gives the language more flexibility to maneuver over the concepts of the world. Different quantifying expressions, inheritance relationships, cardinality restrictions, etc. can be explicitly expressed in KAoS thanks to the constructs of OWL. It also enables KAoS to perform static conflict resolution and policy disclosure. KAoS has its classes and properties already defined in OWL ontologies, referred to as KAoS Policy Ontologies (KPO) (Uszok, et al., 2003), which are accessible from (Uszok & Bradshaw).

Looking back to the similarities and differences discussed, providing meaningful transformations from/to a web rule language to/from a policy language is not a trivial goal. Aside from all the difference in the syntax of the source and the target language, the transformations should care about the underlying logic that each policy language adheres to. As we discussed above, Rei and KAoS follow different logical formalisms, and thus different mapping considerations require to be done in choosing the appropriate elements in the target language to model the elements of the source language. This helps with capturing the logical semantics of the transformed rules. Furthermore, the concepts that might be missed in the procedure of transformation, due to a logical or conceptual mismatch between the policy language and the web rule language, need to be considered (we discuss it further in the next section). Web rule languages have been design with a broad consideration on the supported logic and required logical elements such that they can capture all various types of rules. However, the mismatch in the logics or the concepts may happen when transferring a rule from a web rule language to a policy language. The concepts that result in a logical or conceptual mismatch must be carefully monitored during the process of transformation. Having the lost information during the process of transformation found, the importance of such elements and the harms and threats that may happen to the resources due to information loss might be taken into consideration.

Relations between Policies, Rules, and First Order Logic (FOL)

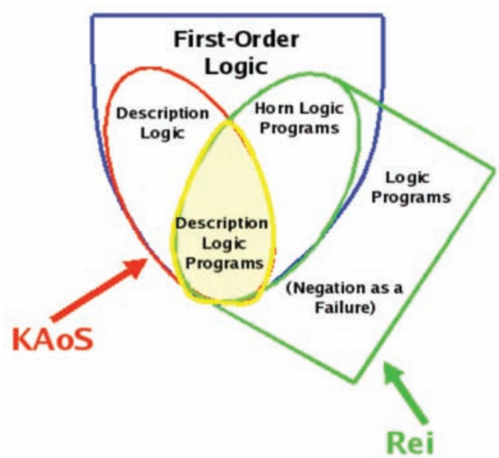
As already mentioned, rules are among the most frequent techniques for representing knowledge. Different knowledge representation methods (including rules in a broader and policies in a narrower sense) typically follow different logical formalisms. A clear use of Web rule languages in place or in conjunction with policies requires a clear understanding of the logical formalisms behind defining rules and policies. There are two major fragments to FOL that are mainly used for representing knowledge, namely, *description logic (DL)* and *computational logic programs (LP)*. Description Logic is a subset of the well-known First Order Logic (FOL) without function symbols (Grosof, Horrocks, Volz, & Decker, 2003), which is similar to a fragment of Horn FOL, *def-Horn*, that also contains no function symbols. LP, however, represents a set of logical constructs that neither includes nor is fully included by FOL but only intersects with it. That is to say, although LP and FOL share some logical constructs, there are concepts in either of the two sets that are missing or do not have any exact equivalent in the other set. For example, FOL can express positive disjunctions (see Grosof, Horrocks, Volz, & Decker, 2003, for details), which are inexpressible in LP. Additionally, various important features and logical elements of LP, which are frequently used in practical rule-based applications, are inexpressible in FOL (e.g. Negation-as-Failure) (Grosof, Horrocks, Volz, & Decker, 2003).

As we mentioned earlier, transformation of rules (or policies) from one language to another requires an accurate syntactic and semantic mapping of the concepts of the source language to the concepts of the target language. Not only does this require a syntactic analysis of the two languages, but also requires capturing the semantics of the rules (or policies), the representation of the domain knowledge, and also the underlying logic of each rule (or policy) language. We have already described that policy languages may come with different logical formalisms, for example KAoS is based on DL while Rei is based on LP. The set of logical constructs for web rule languages is rich enough to capture the concepts of a policy language regardless of whether it follows DL or LP. In such cases, the obtained web rule would admit to the same logical formalisms that the source policy language follows. Nonetheless, when transforming rules from a web rule language to a policy language, it becomes very important to identify the differences in the underlying logic of the source web rule language and the target policy language.

When transforming rules from a DL-based language to an LP-based one, there is no possibility to cover all the concepts. Yet, most of the concepts of these languages are transformable from one to another due to the similarities between DL and def-Horn[1] shown as the intersection of these two sets in Figure 6. Rule transformations, as the major objective followed by RIF and Web rule languages, are not only concerned about a syntactic representation of the elements in a rule language, but they also care about the semantics of the rules. Rule languages can capture the semantics of a domain, first by modeling the domain knowledge using the concepts of the rule language and then by benefiting from the underlying constructs that carry different logical semantics ranging from descriptive elements to declarative ones.

Grosof, Horrocks, Volz, and Decker (2003) provide an elaborate method of mapping the basic elements of description logic to declarative logic programs. OWL as a subset of RDFS corresponds to a fragment of classical FOL. It is shown by Grosof, Horrocks, Volz, and Decker (2003) that

Figure 6. Expressive overlap of description logic and logic programs and where Rei and KAoS sit in this classification



OWL elements are convertible to definite Horn FOL elements which in turn are convertible to definite Datalog Logic Programs as a restricted model of Logic Programs (LPs). For example, classes and class expressions are equivalent to FOL formulae with one free variable, and properties (and property expressions when supported by description logic) are equivalent to FOL formulae with two free variables. Classes and property inclusion axioms are also considered as FOL sentences consisting of an implication between two formulae with the free variables universally quantified at the outer level. Table 1 shows a selection of OWL constructs with their corresponding description logic syntax and FOL expressions. Details of the definitions can be found in (Grosof, Horrocks, Volz, & Decker, 2003).

Model Driven Engineering

The main goal of MDE is to switch the focus from low-level implementation details to problem-specific concepts (Schmidt, 2006). The core activity is then to define languages for particular problem domains (*in our case policies*). Metamodeling is an approach used in MDE for defining languages. A metamodel is a model of a modeling language, that is, a metamodel defines a set of sentences that can be expressed in a modeling language (Kühne, 2006). As such, a metamodel can be regarded as an abstract syntax of a language. Since the goal of MDE is also to provide a common framework for processing different modeling languages, it also defines a technical context in which different modeling languages are defined and used, and on top of which different modeling tools are built.

Metamodeling architectures are used as a solution to this issue. Usually, a metamodeling architecture (e.g., OMG's Model-Driven Architecture) is organized in a layered fashion, where typically there are four layers. The top most layer is called metametamodel (and tagged with M3 or

Table 1. Some of the OWL constructors and the equivalent description logic and FOL expressions

OWL Constructor	DL Syntax	FOL Expressions
subClassOf	$C \subseteq D$	$D \leftarrow C$
transitiveProperty	$P^+ \subseteq P$	$\forall\ x, y, z(P(x, y) \wedge (P(y, z)) \rightarrow P(x, z)$
inverseOf	$P \equiv Q^-$	$\forall\ x, yP(x, y) \Leftrightarrow Q(y, x)$
intersectionOf	$C_1 \cap ... \cap C_n$	$C_1(x) \wedge ... \wedge C_n(x)$
unionOf	$C_1 \cup ... \cup C_n$	$C_1(x) \vee ... \vee C_2(x)$
complementOf	$\neg C$	$\neg C(x)$
one of	$(a_1,...,a_n)$	$x = a_1 \vee ... \vee x = a_n$
hasClass	$\exists$P.C	$\exists y(P(x, y) \wedge C(y))$
toCass	$\forall$P.C	$\forall y(P(x, y) \rightarrow C(y))$

L3), and on this layer a metamodeling languages is defined. Most commonly, this language is defined by itself. In a metamodeling architecture, there is typically one and only one metamodeling language defined. Examples are – OMG's standard Meta-Object Facility (OMG), 2008) and Eclipse's Ecore (Budinsky, Brodsky, & Merks, 2003). While the abstract syntax of two languages is slightly different (i.e., it is a reduced part of UML elements related to class models), the graphical concrete syntax of both languages is borrowed from UML class models. The rationale for having only one M3 language is to have a common space for defining modeling languages on the M2 layer. Thus, various modeling languages can be processed in the same way using the same tool set (e.g., APIs, constraint, query, and transformation languages).

Model transformations are also an intrinsic part of MDE, as the idea is to transform M1 models to different platforms or to allow translation for one type of model (e.g., UML) to another (e.g., ODM). MOF Query/View/Transformation (QVT) is the OMG's official standard for model transformations (OMG, 2005).

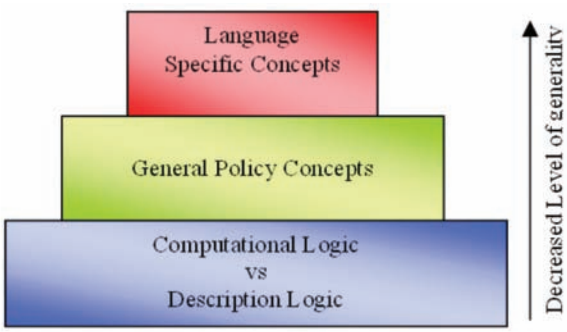
POLICY INTERCHANGE FRAMEWORK

Interchanging the rules in general, and the policies in particular, between different business enterprises is a goal followed by RIF working group (Ginsberg, Hirtle, McCabe, & Patranjan, 2006). We already discussed it in the introduction section why interchanging the policies between different business partners is important to achieve. Nonetheless, the variety of policy languages that have been developed so far, the lack of a standard for defining policies, and the limited number of experts in each of the existing policy languages, made us think about designing a policy interchange framework that can easily expand to cope with different policy languages, especially the ones that have not been developed yet. It is worth noting that while interchanging the policies, we deal with their logic, their abstract syntax, their concrete syntax, the domain in which these policies are deployed, and also the semantics that each term or concept in each language or domain carries. Our studies led us to a point where we realized that, in order to have such a framework, we need to start from the logic that the language follows, to the abstract syntax that it represents, having the semantics of its domain concepts in mind.

One way to represent the domain knowledge is to provide an ontological representation of the domain and form the policy rules around these concepts. The ontological representation of domain concepts brings in all the benefits of Semantic Web into the implementation of policy rules and enables agents from different domains to have shared and common understanding of the concepts of each domain. Consequently, the problem of exchanging policies from one domain to another is divided to two sub-problems of i) transferring the concepts of a domain to the concepts of another domain, and ii) capturing and transferring the logic and the semantics of the language from the source language to the target language. The first sub-problem has already undertaken a lot of research in the field of ontology mapping (Kalfoglou & Schorlemmer, 2003). In this section, we basically illustrate how the second sub-problem can be addressed using web rule languages and this is the second sub-problem that the community of RIF is targeting.

The concrete syntax of the languages is probably the least challenging issue to deal with, as there are powerful transformation tools and languages, such as QVT/ATL (OMG, 2005) and XSLT (Clark, 1999), that can mine through the concrete definition of the languages and extract the appropriate concepts. For the abstract syntax of the language, we normally encounter the general concepts that are shared between the languages with similar purposes, and the language-specific concepts that are not shared between all the languages of one single category. The language-

Figure 7. The layered policy interchange framework architecture



specific concepts take more important roles in languages that are in a lower level of abstraction. Policy languages, due to their characteristics in addressing low level domain specific concepts and the differences in the domains that they need to be deployed in, may have various dissimilar concepts that are specific for each language. A powerful policy interchange framework should be able to clearly distinguish between the logic, the language-independent, and the language-specific concepts and try to have general definitions for as many of these concepts as possible.

Figure 7 shows our proposed architecture for a policy interchange framework. As the figure shows, the policy framework, first starts with identifying the similarities and dissimilarities between the underlying logics of the policy languages. The two main logics that are widely used in defining rules and representing the knowledge of a domain are computational logic and descriptive logic and there has been already research on how to map the concepts of these two logics (Grosof, Horrocks, Volz, & Decker, 2003) (Kolovski, Hendler, & Parsia, 2007).

The next level in the architecture is to identify the general concepts that are common across policy languages. Once these concepts are recognized, the rules from one source language to one target language can be mapped to some degree, having the domain knowledge plus the language vocabulary identified and mapped. For the language-specific concepts of a source policy language, either it is possible to define the concepts through using a series of concepts from the target language, or simply the concepts are not convertible. Depending on the importance of the meanings that the unmappable concepts carry, the transformation to the target policy language would be successful or unsuccessful. As Figure 7 shows, by moving to the upper levels of the architecture, the generality of the mappings is significantly decreased, such that reusing it for other policy languages becomes impossible in the top most level. Nonetheless, it is possible for the concepts in the lower levels to be shared between different policy languages. To plug a new policy language to the framework, first and foremost, the underlying logic of the policy language should be identified and mapping rules to cover the corresponding concepts should be developed. Moving to the upper level in the architecture, the common policy concepts are identified and mapped to the concepts of the general policy model used. For the top most level, a detailed review of the source policy language by its experts is required to work around the concepts that are not mappable.

In the following sections of this chapter, we try to extract the abstract syntax of KAoS by providing its metamodel, extract the language-independent and language specific concepts that the KAoS policy language covers, and argue how the mapping between this policy language and R2ML can happen without facing serious information loss.

METAMODELING FOR POLICIES AND RULE LANGUAGES

Concept modeling is considered a critical step in better understanding and comprehending the constituents of a system in general, and a language in particular. One of our major intentions in providing the metamodel for KAoS is to hide the low-level details of the language in order to focus on its conceptual characteristics. In this section, we present the UML metamodel for KAoS and contrast it against the common concepts in R2ML that can carry the equivalent meanings for those concepts.

As we mentioned earlier, KAoS exploits the use of Web Ontology Language (OWL) to define its concepts. Thus, providing a meta-model for the language can be done through transforming the OWL definition of the languages to a UML metamodel. There have been several efforts in defining standard mappings from ontology languages to UML. In particular, the Ontology Definition Metamodel (ODM) (ODM, 2003) initiative follows the goal of using OMG's Meta Object Facility (MOF) as a metamodeling language to develop a linguistic metamodel to represent the ontology languages. Although ODM, itself, is still undergoing modifications, we chose to use the current state of ODM to represent Rei and KAoS. However, at some points, based on the needs and the real meaning of the concepts in each language, we had to slightly modify the ODM definition for getting a better reflection of the concepts through using UML constructs.

The Metamodel for KAoS Policy Language

KAoS as a policy language has elements to define and distinguish different types of policies over different resources. Due to space limits, here we only focus on the major concepts in KAoS and show how they can be transformed to their equivalent counterparts in R2ML. Figure 8 represents the types of policies that are covered in KAoS. As Figure 8 shows, a policy in KAoS is either an *AuthorizationPolicy* or an *ObligationPolicy* with each of them further specialized to *PosAuthorizationPolicy*, *NegAuthorizationPolicy*, *PosObligationPolicy*, and *NegObligationPolicy*. It can also be a policy over the policies that conflict, *ConflictedPolicies*, which usually is not considered a policy type, but is just a subclass of the class Policy. An *AuthorizationPolicy* introduces the set of permissions and prohibitions for an actor while dealing with a context. However, KAoS is a context-based policy language that defines permissions and prohibitions not over the roles of the actors but over the context of interactions.

In KAoS, each policy element stands for exactly one policy rule. As shown in Figure 9, a KAoS policy can have a control action, a triggering action, an oblige action, and a series of conditions. It also can define a site to which the policy rule should be applied. As we discussed earlier, KAoS is a context based policy language. *This means that the constraints are defined over the actions that are going to be taken on a resource, rather than the users (or roles) that are going to take these actions.* This can be considered as a major difference between the role-based access control policies and the context-based access

Figure 8. Different types of policies in KAoS

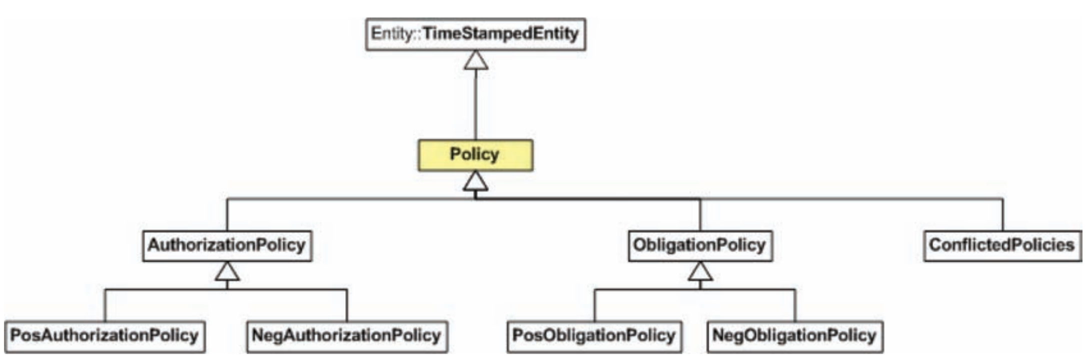


Figure 9. The policy metamodel for KAoS

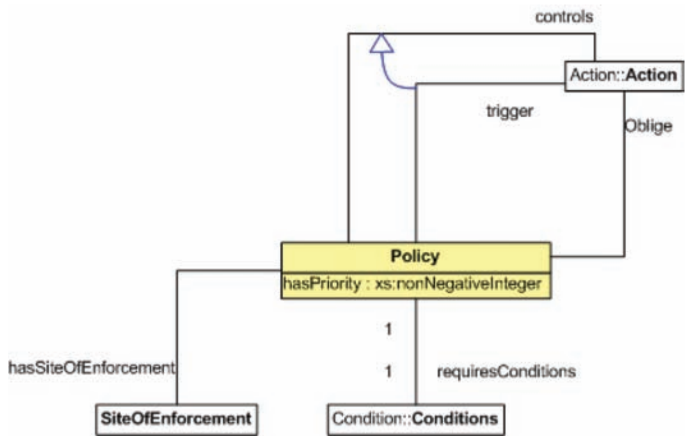

control policies.

An action in KAoS, as shown in Figure 10, has a context to which the action is applied, which either is a *dataContext* of any type (i.e. of type OwlThing), or an *objectContext* of type Target, which is itself an entity. A KAoS action also has one and exactly one Actor, referred to by the *performedBy* property in the definition of the Action. Considering the fact that in context-based policy management Actions are constrained, as opposed to roles in role-based access control, a rich definition for the class Action, its properties, and its attributes helps with having accurate definitions for the constraints and conditions. Having a look at the metamodel in Figure 10, it is clear that KAoS also follows the same objective with defining its actions.

KAoS provides a rich set of actions, inherited from the class Action, that enable better classification and definition of the actions which are going to be performed. This brings more expressivity to the language, enabling a better semantic modeling of each policy. Figure 11 provides a clear classification of all sets of actions that are defined in KAoS. A user can extend any of these classes to make them cope with what she intends to express. *ObligateAction* is one of these important actions in KAoS. An *ObligateAction* makes the active actor

Figure 10. The metamodel for KAoS Action

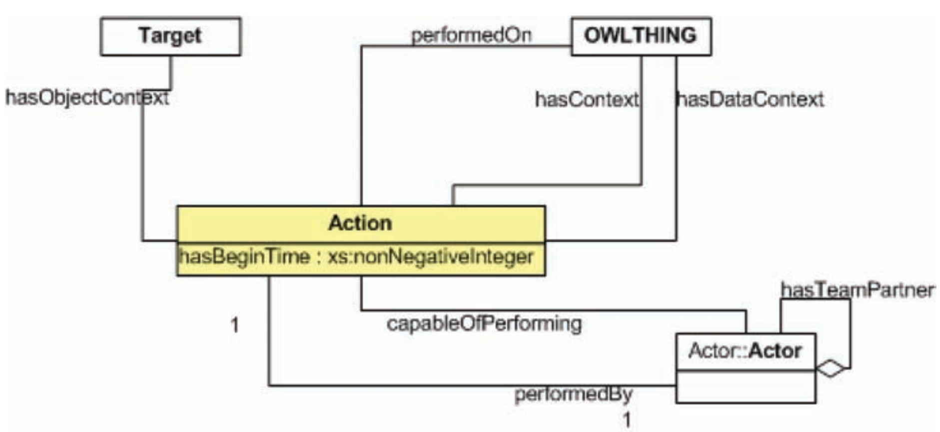

Figure 11. The metamodel for various KAoS action types

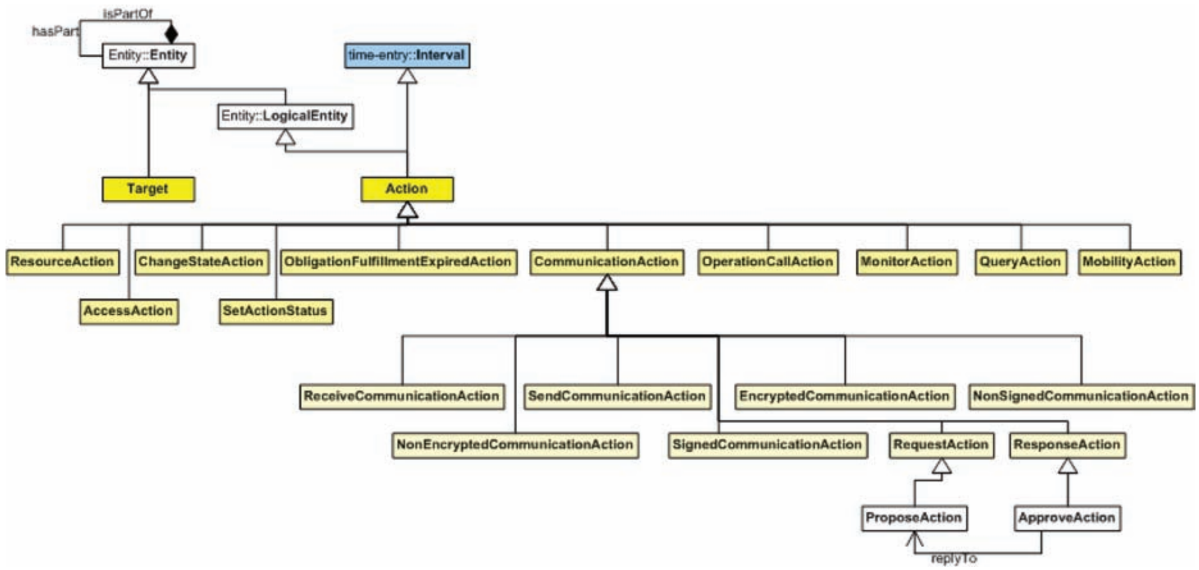

Figure 12. The metamodel for ObligateAction

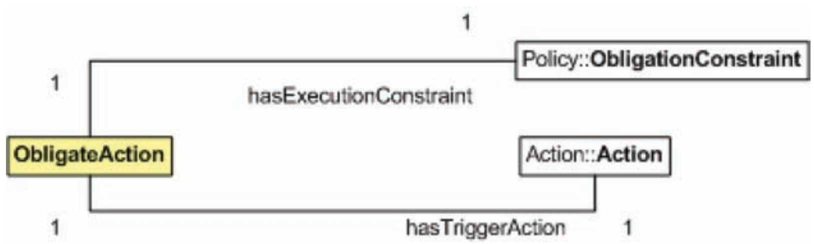

to execute the *ObligateAction* once the triggering action happens and the execution constraints for the obligation action are met (see Figure 12).

In KAoS, similar to the hierarchy of actions, a detailed hierarchy of entities and actors have also been defined. Actors in KAoS, represent a complete set of possible agents that might interact with the system (see Figure 13).

Different physical and artificial actors have been defined by the system which helps with precise classification of the actors while working with policies. The only problem with the obtained model, as we have highlighted in Figure 13, is the redundant definition of both Human and Person which seem to be identical. The reason behind distinguishing between these two concepts by the developers of KAoS is not clear to the authors of this article. Furthermore, according to the ontology definition of KAoS for the concept Human, it inherits from both Person and *PhysicalActor*. Since Person itself has been already defined as a subclass of *PhysicalActor*, the inheritance from *PhysicalActor* by Human seems to be redundant.

An actor in KAoS can be controlled by a set of policies, and is capable of performing a series of actions. It can also cooperate with other actors as a team (see Figure 14).

For a policy to be able to control the behaviour of a system, conditions are required to be place on either potential roles (in case of role-based access control) or potential actions (in case of context-based access control) in a system. A condition in

Figure 13. The metamodel for class Actor in KAoS

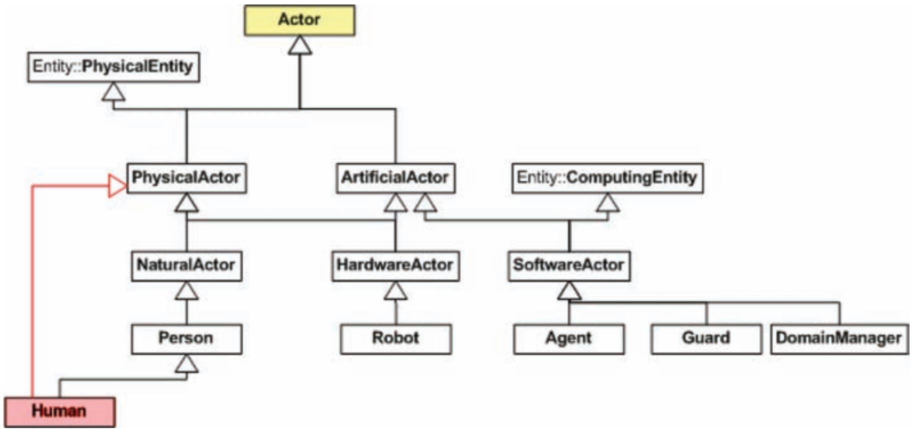

Figure 14. The metamodel for the class Actor in KAoS

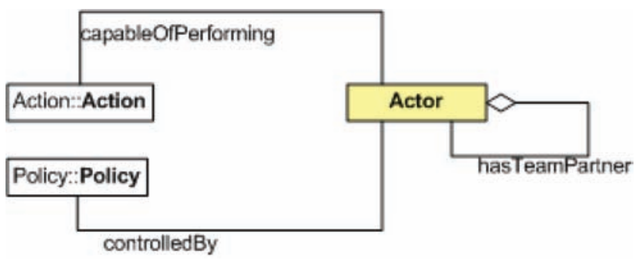

KAoS represents a situation based on the current State and the history of the events (see Figure 15). As Figure 16 shows, the EventHistory keeps the time-stamped events that are mostly in the form of occurred actions, represented in the *Action-History* class. To each *ActionHistory*, relates a *hasRegisteredAction* which represents the current action occurred in each time interval, the actor of the action, and the context to which the action has been applied.

Conceptual Mapping of KAoS and R2ML

Given a rather comprehensive representation of KAoS and R2ML (both syntactically and semantically), we can take the main step in defining the mappings between these two languages, aiming at providing an exchange method between different concepts of these languages. It should be noted that although we deal with the syntactical mapping of the elements, the process of mapping considers semantic similarities as well. In this section, we show that, despite having several possibilities to map the elements of one language to the elements of another language, we choose those elements which are most similar semantically. Our mappings in this section follow the *QVT's graphical notations* (QVT, 2005) for transforming between concepts. However, we have included some dashed arrow lines to make the one-to-one mappings easier to understand.

In our introduction to R2ML, we presented the major types of rules that R2ML covers. Among all the rules, *derivation rules* seem to be better options to model the policies, mostly because they entail the meaning of: "obtaining a conclusion upon satisfaction of a set of conditions (or

Figure 15. The metamodel for conditions in KAoS

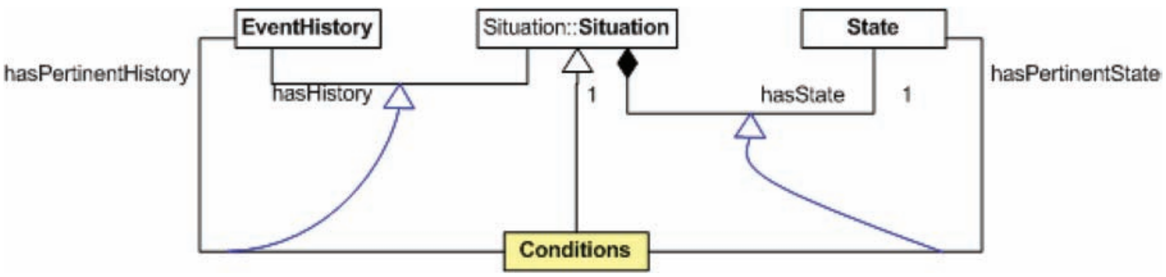

Figure 16. The metamodel for KAoS Situation

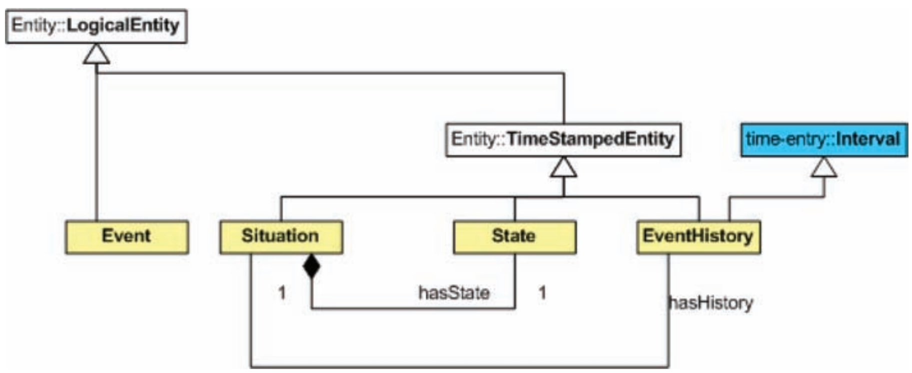
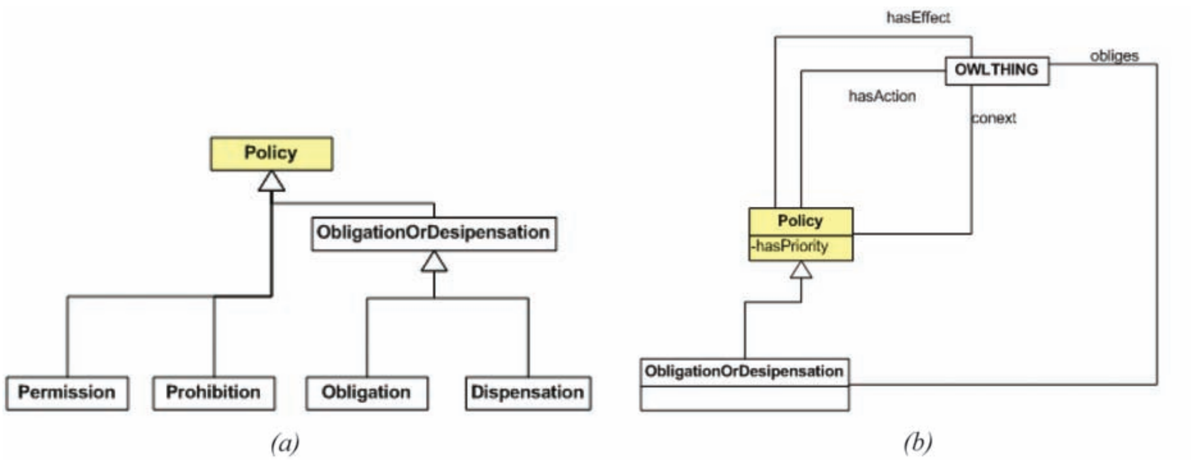


credentials)". Using *implication* in *integrity rules* makes them quite close to our intentions too, but as we already mentioned, integrity rules are generally used where the set of conditions of the rule are persistent over time. *Reaction rules* can be used to reflect the pre- and post-conditions of a policy rule, especially while communicating with Web services. Nonetheless, we believe the intention in using policies is closer to the meanings expressed by derivation rules, i.e. deriving the conclusions once the conditions are met. Thereupon, we choose to use *derivation rules* in order to model policy languages. Some other research works covering this same area are available in (Kaviani et al., 2007-1) and (Kaviani et al., 2007-2).

In our representation of different types of policies for KAoS (see Figure 8), we showed that there are generally four main types of policy rules that these languages support, i.e. *PosAuthorizationPolicy*, *NegAuthorizationPolicy*, *PosObligationPolicy*, and *NegObligationPolicy*. To be able to model these concepts in R2ML, we decided to define some general classes for these types of policies using R2ML. Due to the simplicity of the naming for the policies in Rei, we chose the same set of names to define our policy classes in R2ML. We have also mentioned that R2ML has its own mechanisms for defining vocabularies (also called R2ML vocabulary), so it is possible to exploit R2ML vocabulary to define these policy concepts. Figure 17 show the metamodels for the class *Policy* and its subclasses that we have defined in R2ML. As it can be seen in the models, these classes have simple definitions at the moment which currently seem satisfactory for our purpose. However, the metamodels for these concepts are developed in our recent work, aiming at providing a Policy Modeling Language by using R2ML (Wagner, Giurca, & Lukichev, 2005). Again it should be noted that the (Tonti,

Figure 17. The metamodels for our R2ML Policy classes



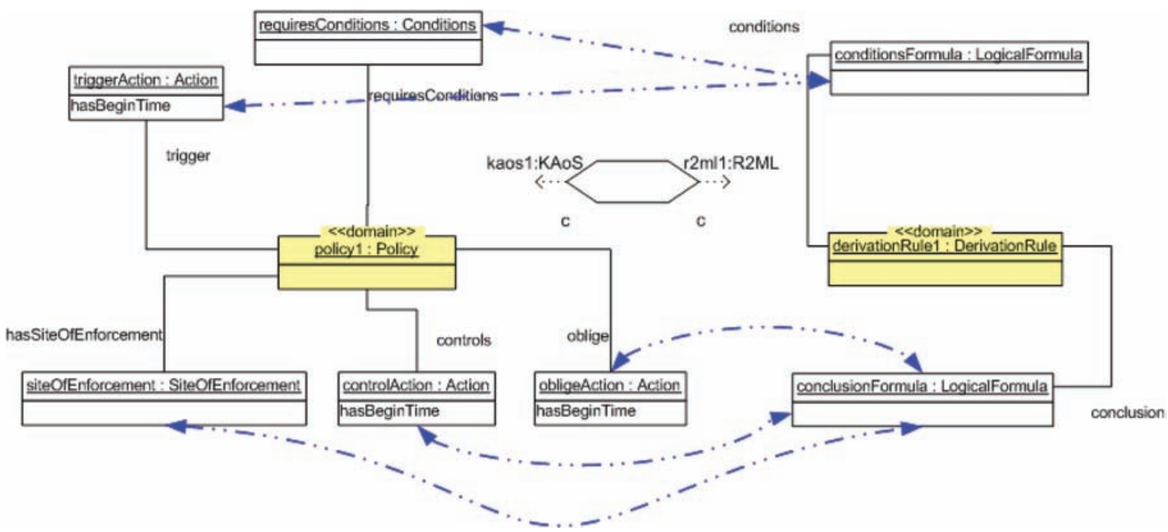
Bradshaw, Jeffers, Montanari, Suri, & Uszok, 2003) properties of these general R2ML-Policy classes do not have any range and they refer to any available resource. This is mainly to increase the flexibility of our R2ML classes to work with different actions and policies from different policy languages. We may decide to make them more restricted in the future.

While transforming each single policy rule from KAoS to R2ML, we decide about how to map these policies to R2ML policies by choosing the same naming conventions that we introduced at the beginning of this section. Next, we describe how the concepts of R2ML along with the classes that we defined above, are jointly used to provide a meaningful mapping between the concepts of the two policy languages.

We have previously mentioned that a KAoS policy is an object of the Policy class in KAoS Policy Ontology (KPO) (Tonti, Bradshaw, Jeffers, Montanari, Suri, & Uszok, 2003) with its attributes instantiated to a set of users, events, and resources that make the policy fire. Considering the KAoS policy element as a rule, the *control* element is executed upon the occurrence of the events described in the *requiresConditions* element (Figure 9). The *control* element in KAoS refers to an action. It can itself place a series of constraints on the definition of the action that can be executed by the policy. The main advantage in using KAoS is its flexibility of expansion. The *Action* class in KAoS can be easily expanded thanks to the use of OWL, to fully capture the meaning of the final action that is desired to be executed. Placing constraints on different properties of this action can also specialize the meaning that is desired to be transformed.

Once a KAoS policy rule is fired, the decision over whether or not to perform the action of the *control* element is made, an obligation of execution is placed over the *obligation* action, and the *effect* of the action is enforced to the current state of the system. This means, to model a KAoS policy with a derivation rule, we need to place the content of the *controls* element, the *oblige* element, the *hasSiteOfEnforcement* element, and the *effect* element (if there is any) in the conclusion part of the derivation rule. Whatever else that can lead to making such a decision should be placed in the condition part of a derivation rule. This includes the content of the *requiresConditions* element, the *triggerAction*, and also the variables that initialize the values for the elements in the conclusion of a rule (see Figure 18). Figure 18 shows the transformation of a KAoS policy rule to a derivation rule in its most abstract model.

Figure 18. Mapping rule of a KAoS Policy to a R2ML derivation rule



The main issue is to decide how and using what R2ML elements this process of transformation can be best achieved. The conclusion of a derivation rule should be only one R2ML *Atom*, now the question is how to manage all the actions in one single *Atom*.

The first step in transforming a KAoS policy rule to a R2ML derivation rule is to transform those elements of the KAoS *Policy* class that are placed in the conclusion part of our R2ML rule, represented with a policy *objectDescriptionAtom*. An instantiation of the derived R2ML policy class will be placed as a conclusion in the derivation rule. Figure 19 shows how this mapping can happen. The *ObjectDescriptionAtom* that captures the meaning of a policy element has four slots. One is the *hasPriority* element which if of type integer and represents a numeric value for the priority of the rule. The other three slots represent object elements that show the action that the policy controls (i.e. *hasAction*), the context to which the policy is applied, and the optional action that the policy may oblige the actor to do.

As earlier argued, an R2ML ObjectDescriptionAtom describes a set of properties and attributes, referred to as *slots*, for an object called the *subject*. As for the policy rules, the conclusion of a policy rule is a policy element (or object) with the values for the appropriate action to be taken, the actor to which giving the permission is allowed or denied, the context to which the policy is applied, and the priority of the policy rule. As a result, an *ObjectDescriptionAtom*, with a policy object as its subject is the best element to model the conclusion of a derivation rule. Figure 20 shows how we instantiate a policy object from our *R2ML Policy* class. It illustrates how the policy object is mapped to the subject of the R2ML *ObjectDescriptionAtom*, the corresponding class for this atom is set to the *Policy* class and different attributes and properties for a policy object are mapped to corresponding *ObjectTerms* or *DataTerms* depending on whether the attribute is a *DataAttribute* or *ObjectAttribute*. It has also been shown in Figure 20 that an *ObjectDescriptionAtom* can have several slots to cover various of data or object attributes for a policy. It makes it the appropriate R2ML element, both syntactically and semantically, to be used for the purpose of transforming between the objects of the policy rules. It should be taken into consideration that, in Figure 20, we are just showing the transforma-

Figure 19. Mapping a KAoS Policy class to an R2ML policy model

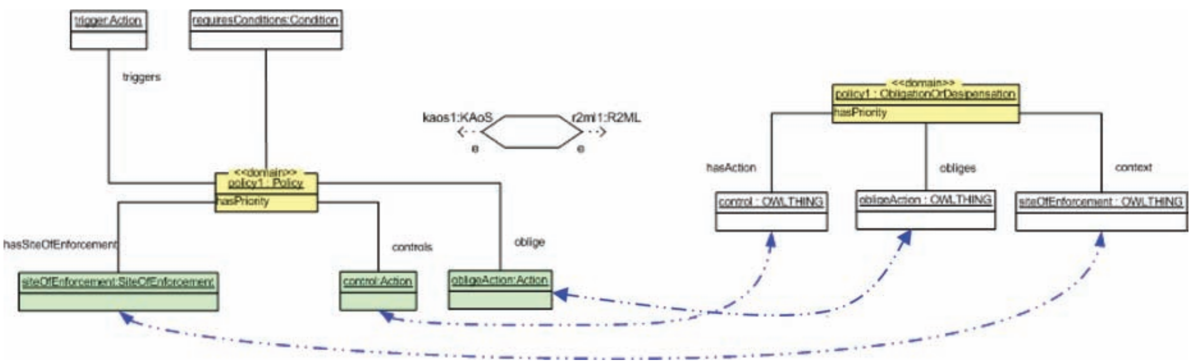


Figure 20. Mapping a KAoS Policy class to R2ML ObjectDescriptionAtom

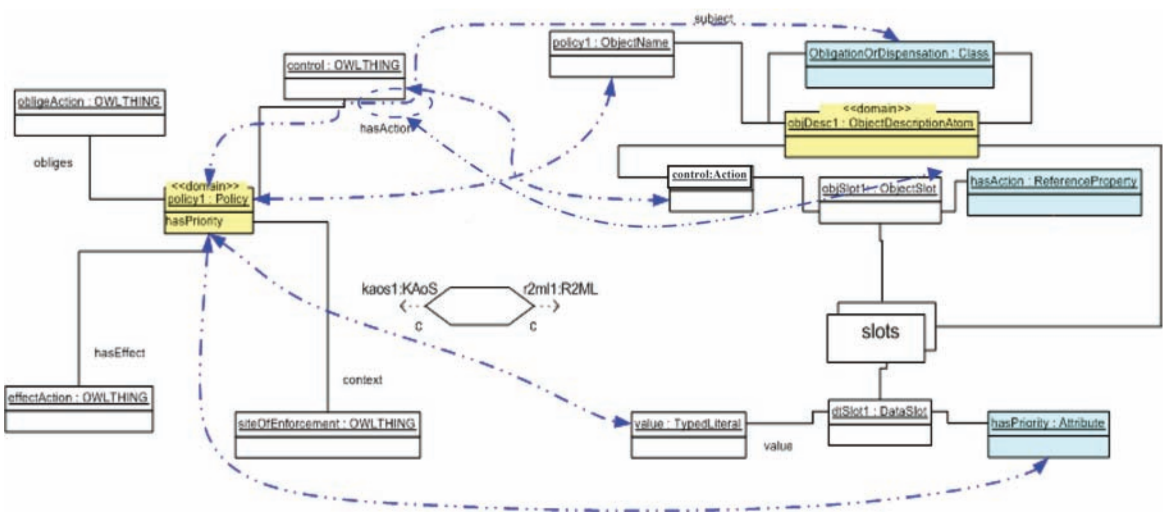


tion of the control element to a slot in the policy *ObjectDescriptionAtom* with the property name *hasAction* represented as a *ReferenceProperty* and the corresponding object to this property (*control* in Figure 20) placed in the body of the slot.

However, referring to Figure 8, one should note that the class Policy is an *abstract* class, and so is our R2ML Policy definition of Figure 17. Thus, in Figure 20, the class Policy is usually replaced with one of its concrete sub-classes, i.e. *Permission*, *Prohibition*, *Obligation*, or *Dispensation*

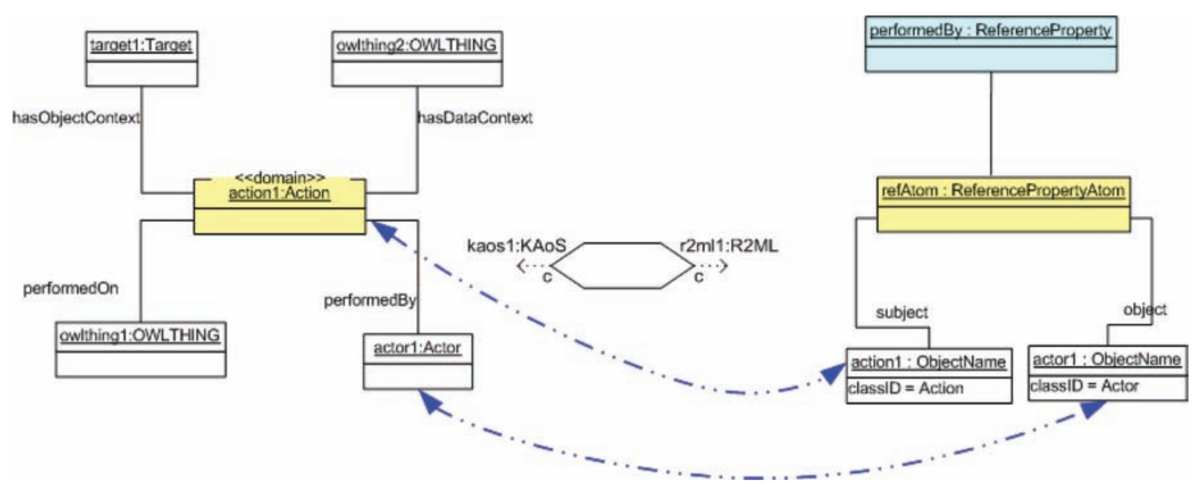
Having the conclusion of our derivation rules constructed, we need to extract its condition part from KAoS policy rules as well. The condition part of a policy derivation rule contains the definition of the variables, actions, actors, conditions, and any other construct that result in deriving the final policy object. Although the conditions of a policy rule could be modeled with *ObjectDescriptionAtoms*, we chose *ReferencePropertyAtoms* mainly to be compliant with other R2ML transformations (e.g., transformations between F-Logic and R2ML also have *ReferencePropertyAtom* in the condition part). It simplifies the later conversions of the policies to other rule languages for which we have R2ML transformations already defined (e.g., Rei, F-Logic, and RuleML). On the other hand, a *ReferencePropertyAtom* triple models a binary predicate. A set of *ReferencePropertyAtoms* with the same subject element can always be combined and converted to any element of higher arity (e.g. *ObjectDescriptionAtom*), and thus using *ReferencePropertyAtom* does not contradict the use of *ObjectDescriptionAtom*. Furthermore, in our case, *ReferencePropertyAtoms* carry even a better semantic meaning for the transformations. Semantically, they are equivalent to an OWL object property, and as KAoS is semantically very close to OWL, they model object properties of KAoS too. Figure 21 shows the conversion of a KAoS property (here, the *performedBy* property) to a *ReferencePropertyAtom* in R2ML. The converted element is then placed in the *conditions* part of a derivation rule.

In some cases, it happens that all the objects are not named-objects, but rather, they refer to *ObjectVariables*. In KAoS, due to the impossibility of representing variables in OWL, a *role-value-map* method is used in which a class representing the set of possible elements for a slot replaces the object variable in order to show all the possible options an element can take. The transformation procedure should recognize these classes and convert them to appropriate R2ML elements. This happens in two steps during our mappings. Once the role-value-mapped class is determined, it is first mapped to an *ObjectClassificationAtom* with a variable name assigned to it, and then the variable is used in place of the required elements for the class, for example in a *ReferencePropertyAtom*. Figure 22 shows the conversion of a role-value-map class to a R2ML *ObjectClassificationAtom*. In this figure, the generated variable *X* shows the variable that later can be used in other places in the rule.

For example, in case we need to convert it to the *ReferencePropertyAtom* of Figure 21, the only change would be to replace *actor1* with *X*. It should be highly noted that, an *ObjectClassificationAtom*, representing a variable, always needs to be placed in the condition part of the derivation rule, even if the variable needs to be used in the conclusion part. Figure 23 also shows another example of how the combination of *ObjectClassificationAtom* and *ReferencePropertyAtom* can be used to define a class of actors in KAoS

A KAoS policy might also have a *trigger action*. To the best of our knowledge, this element is only used with *NegObligation*- and *PosObligation-Policies* showing a set of events that trigger the occurrence of an action. In our *R2ML Policy* model, we have considered a slot for these actions.

Figure 21. The abstract transformation of a KAoS property to a R2ML ReferencePropertyAtom



Furthermore, the detailed information about these actions is defined as *ReferencePropertyAtoms* in the condition part of a derivation rule. Consequently, the same process shown in Figure 21 is also applied to the trigger element, which itself refers to an action. The *obligeAction* element of a KAoS policy is also considered an *ObjectSlot* in the *ObjectDescriptionAtom* of the R2ML Policy object. The *ObjectSlot* refers to the action that should be performed by the actor as an obligation,

once the policy rule is fired.

Having the most important elements of a KAoS policy explained here, we present some of the concrete, XML syntax-based formalization of our transformation rules in Figure 24.

Other elements of the KAoS policy language are placed in the body of a derivation rule. As a result, we perform a conversion to *ReferencePropertyAtom* for those elements. The main reason is to be compliant with Rei. Moreover, once we have the relations defined in the form of RDF triples, then conversion to the predicates of higher arity is a lot simpler, as for *n* triples with similar *subject* we can make one ObjectDescriptionAtom of arity ***n*** by combining all these elements.

AN EXAMPLE OF APPLYING THE TRANSFORMATION RULES TO A KAOS POLICY

To this point, we have conceptualized and formalized our policy transformation framework. Now that the formalization of our transformations is complete, we can apply our definitions to a real example of the KAoS policy taken from (Toninelli,

Bradshaw, Kagal, & Montanari, 2005). Let us consider a travel agency, named Sky Team that plans to promote its services by giving free printing access to those of its customers located in any of the gates of 31 to 57 at the local airport. Figure 25a shows the KAoS representation of this policy. The policy is a PosAuthorizationPolicy and instantiates hasSiteOfEnforcement and hasPriority.

As already stated, we define four main policy classes for our policy rules, including, *Permission*, *Prohibition*, *Obligation*, and *Dispensation*. The first step in providing the mappings is to determine the appropriate R2ML classes and elements that can be used according to our definitions in the previous section. A *PosAuthorizationPolicy* in KAoS is equivalent to our definition of the *Permission* class in R2ML. Having a KAoS policy element necessitates the definition of an *ObjectDescriptionAtom* to describe its properties, which should be placed in the conclusion part of a derivation rule. The *ObjectDescriptionAtom* takes the name of the policy instance as its *subject* and is considered as an instance of the *Permission* class that we defined in the previous chapter. The *hasSiteOfEnforcement* property from a KAoS policy is modeled as an *ObjectSlot* for our *ObjectDescriptionAtom* with its *referencePropertyID* referring to *context* according to our definition of R2ML Policy class. The *hasPriority* attribute in KAoS has an equivalent *hasPriority* element in our R2ML Policy model which is considered as a *DataSlot*.

In our example, we have a PrinterAccessAction as a subclass of AccessAction for which we have the metamodel illustrated in Figure 26. As the figure shows, accessedEntity is the subProperty of hasObjectContext and thus the class that this property refers to (i.e. Printer31-57 in our example) plays as the context for the PrinterAccessAction.

Having a look at the SkyTeamGate31-57PrinterAccessAction class, as the to-be-controlled class, we realize that SkyTeamCustomer, Printer31-57, and AccessAction are OWL classes. To be able to place these elements in the conclusion part of a derivation rule, we need to associate the classes with variables which show the extensional meaning of the classes. The object for *hasAction* refers to variable *X*. *ObjectClassificationAtoms* seem to be appropriate R2ML constructs to connect a variable to its class name. However, they need to be placed in the condition part of the derivation rule. Getting to this point, we have mapped almost everything in Table 3a to R2ML, but Table 3 provides a description for the class SkyTeamCustomer, considering it as a subclass of the class Customer with its firm property only limited to the class SkyTeamAlliance. As it is a descriptive class, it should be placed in the condition part of a derivation rule, and *ObjectDescriptionAtom* is probably the best element to map this class to.

Figure 26. The KAoS metamodel for AccessAction

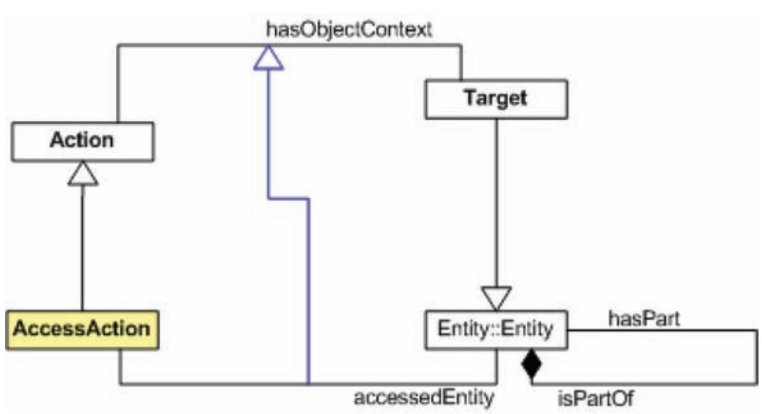

Table 3b shows the full transformation of this KAoS policy to its equivalent R2ML code based on the provided descriptions

DISCUSSION AND CONCLUSION

In this last section, we analyze the transformations that we have explained so far, we show how these transformations can be used together with other transformations that have been already developed for R2ML based on derivation rules, and we discuss the possibility of using them to convert our policy-driven R2ML rules to the rule languages that are supported by those policy languages

Compatibility of our Transformations with other R2ML Transformations

As we already stated, R2ML is supposed to be an intermediary language, to/from which other policy languages can be transformed. To achieve this goal several transformations have been defined and developed between R2ML and other rule languages by mapping the rules from these languages to one of four main types of rules that R2ML supports, i.e. *derivation rules*, *integrity rules*, *production rules*, and *reaction rule*s. Table 2 shows the current transformations that have been developed between R2ML and other rule languages as well as their corresponding R2ML rules which have been used. As our transformations of policy rules to R2ML are converted to its subset of derivation rules, we can use the currently existing transformation of derivation rules to convert our policies to the rules in any of the target languages (i.e., RuleML, Jess, Jena, and F-Logic).

Information Loss During Policy Transformation

Information loss happens in most transformations between different policy languages due to the differences in their underlying concepts. However, in our model, regardless of the policy language that is being used, the concepts can be mapped to R2ML thanks to the rich set of elements that R2ML supports for different logical bases. For example, the concept of *Domain* from KAoS can be covered by extending our R2ML Policy model of Figure 17, yet it should be investigated how these concepts are effective and useful when they are shared between different policy languages. Extending R2ML by the concepts from different policy languages under study does not make the whole model more generic, but it reduces the expressivity when coping with the abstract notation of different policy languages. This implies that the more we try to adjust our R2ML policy model to one policy language, the more it will be diverged

Table 2. Transformations between R2ML and other Rule Languages. Right arrows explain transformations from R2ML to these languages while double head arrows explain transformations between R2ML and the language in both directions

from adjusting to the concepts of other policy languages. Extensions to a policy model should be done carefully and after deeply reviewing the pros and cons of the newly added concepts. There is a tradeoff between supporting the semantics of one policy language and being able to cope with the semantic of other policy languages, which if not carefully designed, would render the R2ML policy model useless.

To be able to check the feasibility of the transformations in protecting the resources, a deeper analysis should be conducted. The most promising approach would be to deploy the policies on different resources and broker agents and get them to communicate. The level of jeopardizing the resources and the to-be-protected contents should be carefully examined. Policies are the critical rules in a business system which regulates the behavior of the system. Any flaw or miss-interpretation of the policies may result in the non-compostable loss of data and information. This further necessitates a detailed examination of the policies while working on the level of policy exchange. The practical analysis of the transformed policies is part of the upcoming research project that will be conducted in the Laboratory for Ontological Research (LORe) at Simon Fraser University

This book chapter demonstrated the possibility to exchange the policy languages by *1) high level metamodel representation of their concepts*, *2) capturing the semantics of the concepts*, *3) identifying the similarities and dissimilarities of the modeled concepts*, and *4) applying the transformations to the concrete syntax of the policy language, benefiting from the QVT representation of the transformations*. All the above steps are compliant with the required steps in software design using MDE techniques (Schmidt, 2006). Using MDE techniques to provide the transformations significantly assists with having valid models for the source and the target languages. Furthermore, while using MDE, we are able to detect the inconsistent or missing constructs of different languages. During working with policies we discovered some points of improvement for R2ML which can add to its efficiency. First of all, we found that it is important for rules to have a value as an indicator for their priority. Having a set of rules, as in R2ML derivation or integrity rule sets, we need to provide an indicator of how one rule in this series can be chosen over the other ones. It especially helps with cases where more than one rule might be applicable to a certain situation. Although this issue matters mainly at the level of rule enforcement, where the enforcement engine needs to select among a set of applicable rules, and knowing that the current versions of R2ML are not supposed to be used at any enforcement level, dealing with rule exchange for cases where the source or the target rules need to have priorities makes it necessary to have priority indicators for the rules.

Another point that seems to be open to extend in R2ML is the possibility to use quantifiers to express cardinality. While working with KAoS, we realized that this language supports *min_cardinality* and *max_cardinality*. However, these quantified formulas are not possible to be used in the condition of a derivation rule set as the elements of the condition part are considered quantifier free and should be universally quantified. An extension to R2ML such that cardinalities can be supported in the condition of the derivation rules (and possibly other types of rules) has been also considered as a potential improvement in the next version of R2ML. Further to this, there have been long discussions on whether derivation rules or integrity rules should be used to model the policies. Looking back at the definitions of integrity and derivation rules, we see that integrity rules define that something *must necessarily* hold, or it *should* hold, while derivation rules carry a derivative meaning representing a set of new conclusions based on the presented facts. Both of these types of rules can be used to define the policies depending on the type and the purpose of the policy (i.e. authorization, authentication, and Quality of Service).

KEY TERMS AND DEFINITIONS

KAoS: KAoS language is a multi-paradigm specification language with a two-level structure: an outer semantic net layer for declaring concepts, their attributes and links to other concepts and an inner formal assertion layer for formally defining the concept.

MDA: an approach to application design and implementation that encourages efficient use of system models in the software development process, and it supports reuse of best practices when creating families of systems.

MOF 2: a metadata management framework, and a set of metadata services that enable the development and interoperability of model- and metadata-driven systems.

OWL: Web Ontology Language designed for use by applications that need to process the content of information instead of just presenting information to humans. OWL can be used to explicitly represent the meaning of terms in vocabularies and the relationships between those terms. This representation of terms and their interrelationships is called an ontology.

QVT: a standard for model transformation languages

R2ML: a MOF-defined general rule language that captures integrity, derivation, production, and reaction rules. It is a well-known proposal for RIF.

RIF: Rule Interchange Format is W3C initiative that should define an intermediary language between various rule languages, but it should not provide a formally defined semantic foundation for reasoning on the Web such as OWL for ontologies.

ENDNOTE

Chapter 7.19
Scalable Authoritative OWL Reasoning for the Web

Aidan Hogan
National University of Ireland, Ireland

Andreas Harth
National University of Ireland, Ireland

Axel Polleres
National University of Ireland, Ireland

ABSTRACT

In this article the authors discuss the challenges of performing reasoning on large scale RDF datasets from the Web. Using ter-Horst's pD* fragment of OWL as a base, the authors compose a rule-based framework for application to web data: they argue their decisions using observations of undesirable examples taken directly from the Web. The authors further temper their OWL fragment through consideration of "authoritative stheirces" which counter-acts an observed behavitheir which we term "ontology hijacking": new ontologies published on the Web re-defining the semantics of existing entities resident in other ontologies. They then present their system for performing rule-based forward-chaining reasoning which they call SAOR: Scalable Authoritative OWL Reasoner. Based upon observed characteristics of web data and reasoning in general, they design their system to scale: the system is based upon a separation of terminological data from assertional data and comprises of a lightweight in-memory index, on-disk sorts and file-scans. The authors evaluate their methods on a dataset in the order of a hundred million statements collected from real-world Web stheirces and present scale-up experiments on a dataset in the order of a billion statements collected from the Web.

INTRODUCTION

Information attainable through the Web is unique in terms of scale and diversity. The Semantic Web movement aims to bring order to this information by providing a stack of technologies, the core of which is the Resource Description Framework

(RDF) for publishing data in a machine-readable format: there now exists millions of RDF data-sources on the Web contributing billions of statements. The Semantic Web technology stack includes means to supplement instance data being published in RDF with ontologies described in RDF Schema (RDFS) (Brickley and Guha 2004) and the Web Ontology Language (OWL) (Bechhofer, van Harmelen et al. 2004; Smith, Welty et al. 2004), allowing people to formally specify a domain of discourse, and providing machines a more sapient understanding of the data. In particular, the enhancement of assertional data (i.e., instance data) with terminological data (i.e., structural data) published in ontologies allows for deductive reasoning: i.e., inferring implicit knowledge.

In particular, our work on reasoning is motivated by the requirements of the Semantic Web Search Engine (SWSE) project: http://swse.deri.org/, within which we strive to offer search, querying and browsing over data taken from the Semantic Web. Reasoning over aggregated web data is useful, for example: to infer new assertions using terminological knowledge from ontologies and therefore provide a more complete dataset; to unite fractured knowledge (as is common on the Web in the absence of restrictive formal agreement on identifiers) about individuals collected from disparate sources; and to execute mappings between domain descriptions and thereby provide translations from one conceptual model to another. The ultimate goal here is to provide a "global knowledge-base", indexed by machines, providing querying over both the explicit knowledge published on the Web and the implicit knowledge inferable by machine. However, as we will show, complete inferencing on the Web is an infeasible goal, due firstly to the complexity of such a task and secondly to noisy web data; we aim instead to strike a comprise between the above goals for reasoning and what is indeed feasible for the Web.

Current systems have had limited success in exploiting ontology descriptions for reasoning over RDF web data. While there exists a large body of work in the area of reasoning algorithms and systems that work and scale well in confined environments, the distributed and loosely coordinated creation of a world-wide knowledge-base creates new challenges for reasoning:

- the system has to perform on web-scale, with implications on the completeness of the reasoning procedure, algorithms and optimisations;
- the method has to perform on collaboratively created knowledge-bases, which has implications on trust and the privileges of data publishers.

With respect to the first requirement, many systems claim to inherit their scalability from the underlying storage—usually some relational database system—with many articles having been dedicated to optimisations on database schemata and access; c.f. (Pan and Heflin 2003; Theoharis, Christophides et al. 2005; Zhou, Ma et al. 2006; Hondjack, Pierra et al. 2007). With regards the second requirement, there have been numerous papers dedicated to the inter-operability of a small number of usually trustworthy ontologies; c.f. (Ghilardi, Lutz et al. 2006; Lutz, Walther et al. 2007; Jiménez-Ruiz, Grau et al. 2008). We leave further discussion of related work to Section 6, except to state that the combination of web-scale and web-tolerant reasoning has received little attention in the literature and that our approach is novel.

Our system, which we call "Scalable Authoritative OWL Reasoner" (SAOR), is designed to accept as input a web knowledge-base in the form of a body of statements as produced by a web-crawl and to output a knowledge-base enhanced by forward-chaining reasoning over a given fragment of OWL. In particular, we choose forward-chaining to avoid the runtime complexity of query-rewriting associated with backward-chaining approaches: in the web search scenario, the requirement for low query response times and resource usage preclude the applicability of query-rewriting for many reasoning tasks.

SAOR adopts a standard rule-based approach to reasoning whereby each rule consists of (i) an 'antecedent': a clause which identifies a graph pattern that, when matched by the data, allows for the rule to be executed and (ii) a 'consequent': the statement(s) that can be inferred given data that match the antecedent. Within SAOR, we view reasoning as a once-off rule-processing task over a given set of statements. Since the rules are all known *a-priori*, and all require simultaneous execution, we can design a task-specific system that offers much greater optimisations over more general rule engines. Firstly, we categorise the known rules according to the composition of their antecedents (e.g., with respect to arity, proportion of terminological and assertional patterns, etc.) and optimise each group according to the observed characteristics. Secondly, we do not use an underlying database or native RDF store and opt for implementation using fundamental data-structures and primitive operations; our system is built from scratch specifically (and only) for the purpose of performing pre-runtime forward-chaining reasoning which gives us greater freedom in implementing appropriate task-specific optimisations.

This article is an extended version of (Hogan, Harth et al. 2008), in which we presented an initial modus-operandi of SAOR; we provided some evaluation of a set of rules which exhibited linear scale and concluded that using dynamic index structures, in SAOR, for more complex rulesets, was not a viable solution for a large-scale reasoner. In this article, we provide extended discussion of our fragment of OWL reasoning and additional motivation for our deliberate incompleteness in terms of computational complexity and impediments posed by web data considerations. We also describe an implementation of SAOR which abandons dynamic index structures in favour of batch processing techniques known to scale: namely sorts and file-scans. We present new evaluation of the adapted system over a dataset of 147m triples collected from 665k web sources and also provide scale-up evaluation of our most optimised ruleset on a dataset of 1.1b statements collected from 6.5m web sources.

Specifically, we make the following contributions in this article:

- We discuss and apply a selected rule-based subset of OWL reasoning, i) to be computationally efficient, ii) to avoid an explosion of inferred statements, iii) to be tolerant to noisy web data and iv) to protect existing specifications from undesirable contributions made in independent locations. That is, our system implements a positive fragment of OWL Full which has roots in ter Horst's pD* (ter Horst 2005) entailment rules and our system includes analysis of the authority of sources to counter-act the problem of ontology hijacking in web data (Section 3).
- We describe a scalable, optimised method for performing rule-based forward-chaining reasoning for our fragment of OWL. In particular, we refine our algorithm to capitalise on the similarities present in different rule antecedent patterns and the low volume of terminological data relative to assertional data. We implement the system using on-disk batch processing operations known to scale: sorts and scans (Section 4).
- We show experimentally that a forward-chaining materialisation approach is feasible on Web data, showing that, by careful materialisation through our tailored OWL ruleset, we can avoid an explosion of inferred statements. We present evaluation with respect to computation of our most expressive ruleset on a dataset of 147m statements collected from 665k sources and present scale-up measurements by applying

our most optimised ruleset on a dataset of 1.1b statements collected from 6.5m sources. We also reveal that the most computationally efficient segment of our reasoning is the most productive with regards inferred output statements (Section 5).

We discuss related work in Section 6 and conclude with Section 7.

PRELIMINARIES

Before we continue, we briefly introduce some concepts prevalent throughout the article. We use notation and nomenclature as is popular in the literature, particularly from (Hayes 2004).

RDF Term

Given a set of URI references $\mathcal{U}$, a set of blank nodes $\mathcal{B}$, and a set of literals $\mathcal{L}$, the set of *RDF terms* is denoted by $\mathcal{RDFTerm} = \mathcal{U} \cup \mathcal{B} \cup \mathcal{L}$. The set of blank nodes $\mathcal{B}$ is a set of existensially quantified variables. The set of literals is given as $\mathcal{L} = \mathcal{L}_p \cup \mathcal{L}_t$, where $\mathcal{L}_p$ is the set of plain literals and $\mathcal{L}_t$ is the set of typed literals. A typed literal is the pair $l = (s, t)$, where s is the lexical form of the literal and $t \in \mathcal{U}$ is a datatype URI. The sets $\mathcal{U}$, $\mathcal{B}$, $\mathcal{L}_p$ and $\mathcal{L}_t$ are pairwise disjoint.

RDF Triple

A triple $t = (s, p, o) \in (\mathcal{U} \cup \mathcal{B}) \times \mathcal{U} \times (\mathcal{U} \cup \mathcal{B} \cup \mathcal{L})$ is called an *RDF* triple. In a triple (s, p, o), s is called subject, p predicate, and o object.

RDF Triple in Context/RDF Quadruple

A pair (t, c) with a triple $t = (s, p, o)$ and $c \in \mathcal{U}$ is called a triple in context c (Guha, McCool et al. 2004; Harth and Decker 2005; Prud'hommeaux and Seaborne 2008). We may also refer to (s, p, o, c) as the RDF quadruple or quad q with context c.

We use the term 'RDF statement' to refer generically to triple or quadruple where differentiation is not pertinent.

RDF Graph/Web Graph

An *RDF graph* $\mathcal{G}$ is a set of *RDF t*riples; that is, a subset of $(\mathcal{U} \cup \mathcal{B}) \times \mathcal{U} \times (\mathcal{U} \cup \mathcal{B} \cup \mathcal{L})$.

We refer to a *web graph* $\mathcal{W}$ as a graph derived from a given web location (i.e., a given document). We call the pair $(\mathcal{W}, c)$ a web-graph $\mathcal{W}$ in context c, where c is the web-location from which $\mathcal{W}$ is retrieved. Informally, $(\mathcal{W}, c)$ is represented as the set of quadruples (t_w, c) for all $t_w \in \mathcal{W}$.

Generalised Triple

A triple $t = (s, p, o) \in (\mathcal{U} \cup \mathcal{B} \cup \mathcal{L}) \times (\mathcal{U} \cup \mathcal{B} \cup \mathcal{L}) \times (\mathcal{U} \cup \mathcal{B} \cup \mathcal{L})$ is called a *generalised triple*.

The notions of generalised quadruple, generalised statement and generalised graph follow naturally. Our definition of "generalised" is even more liberal than that described in (ter Horst 2005) wherein blank nodes are allowed in the predicate position: we also allow literals in the subject and predicate position. Please note that we may refer generically to a "triple", "quadruple", "graph" etc. where a distinction between the "generalised" and "RDF" versions is not pertinent.

Merge

The merge $M(\mathcal{S})$ of a set of graphs $\mathcal{S}$ is the union of the set of all graphs $\mathcal{G}'$ for $\mathcal{G} \in \mathcal{S}$ and $\mathcal{G}'$ derived from $\mathcal{G}$ such that $\mathcal{G}'$ contains a unique set of blank nodes for $\mathcal{S}$.

Web Knowledge-Base

Given a set $\mathcal{S}_{\mathcal{W}}$ of RDF web graphs, our view of a web knowledge-base $\mathbb{KB}$ is taken as a set of pairs $(\mathcal{W}', c)$ for each $\mathcal{W} \in \mathcal{S}_{\mathcal{W}}$, where $\mathcal{W}'$ contains a unique set of blank nodes for $\mathcal{S}_{\mathcal{W}}$ and c denotes the *URL* location of $\mathcal{W}$.

Informally, $\mathbb{KB}$ is a set of quadruples retrieved from the Web wherein the set of blank nodes are unique for a given document and triples are enhanced by means of context which tracks the web location from which each triple is retrieved. We use the abbreviated notation $\mathcal{W} \in \mathbb{KB}$ or $\mathcal{W}' \in \mathbb{KB}$ where we mean $\mathcal{W} \in \mathcal{S}_{\mathcal{W}}$ for $\mathcal{S}_{\mathcal{W}}$ from which $\mathbb{KB}$ is derived or $(\mathcal{W}', c) \in \mathbb{KB}$ for some c.

Class

We refer to a class as an RDF term which appears in either:

- o of a triple t where p is `rdf:type`; or
- s of a triple t where p is `rdf:type` and o is `rdfs:Class` or `:Class`[1].

Property

We refer to a property as an RDF term which appears in either:

- p of a triple t; or
- s of a triple t where p is `rdf:type` and o is `rdf:Property`.

Membership Assertion

We refer to a triple t as a membership assertion of the property mentioned in predicate position p. We refer to a triple t with predicate `rdf:type` as a membership assertion of the class mentioned in the object o. For a class or property v, we denote a membership assertion as $m(v)$.

Meta-Class

A meta-class is a class of classes or properties; i.e., the members of a meta-class are either classes or properties. The set of RDF(S) and OWL meta-classes is as follows: { `rdf:Property`, `rdfs:Class`, `rdfs:ContainerMembershipProperty`, `:AnnotationProperty`, `:Class`, `:DatatypeProperty`, `:DeprecatedClass`, `:DeprecatedProperty`, `:FunctionalProperty`, `:InverseFunctionalProperty`, `:ObjectProperty`, `:OntologyProperty`, `:Restriction`, `:SymmetricProperty`, `:TransitiveProperty` }.

Meta-Property

A meta-property is one which has a meta-class as it's domain. Meta-properties are used to describe classes and properties. The set of RDFS and OWL meta-properties is as follows: { `rdfs:domain`, `rdfs:range`, `rdfs:subClassOf`, `rdfs:subPropertyOf`, `:allValuesFrom`, `:cardinality`, `:complementOf`, `:disjointWith`, `:equivalentClass`, `:equivalentProperty`, `:hasValue`, `:intersectionOf`, `:inverseOf`, `:maxCardinality`, `:minCardinality`, `:oneOf`, `:onProperty`, `:someValuesFrom`, `:unionOf` }.

Terminological Triple

We define a *terminological* triple as one of the following:

- a membership assertion of a meta-class; or
- a membership assertion of a meta-property; or
- a triple in a non-branching, non-cyclic path $t_0^r, \ldots, t_n^r$ where $t_0^r = (s_0, p_0, o_0)$ *for* $p_0 \in$ {`:intersectionOf`, `:oneOf`, `:unionOf`}; $t_k^r = (o_{k-1}$, `rdf:rest`, $o_k)$ for $1 \le k \le n$, $o_{k-1} \in \mathcal{B}$ and o_n = `rdf:nil`; or a triple $t_k^f = (o_k$, `rdf:first`, $e_k)$ with o_k for $1 \le k < n$ as before.

We refer to triples $t_0^r, \ldots, t_n^r$ and all triples t_k^f as terminological collection triples, whereby *RDF* collections are used in a union, intersection or enumeration class description.

Triple Pattern, Basic Graph Pattern

A *triple pattern* is defined as a generalised triple where, in all positions, variables from the infinite set $\mathcal{V}$ are allowed; i.e.: $tp = (s_v, p_v, o_v) \in \times (\mathcal{U} \cup \mathcal{B} \cup \mathcal{L} \cup \mathcal{V}) \times (\mathcal{U} \cup \mathcal{B} \cup \mathcal{L} \cup \mathcal{V})$. A set (to be read as conjunction) of triple patterns $\mathcal{GP}$ is also called a basic graph pattern.

We use—following SPARQL notation (Prud'hommeaux and Seaborne 2008)—alphanumeric strings preceded by '?' to denote variables in this article: e.g., ?x. Following common notation, such as is used in SPARQL and Turtle[2], we delimit triples in the same basic graph pattern by '.' and we may group triple patterns with the same subject or same subject-predicate using ';' and ',' respectively. Finally, we denote by $\mathcal{V}(tp)$ (or $\mathcal{V}(\mathcal{GP})$, resp.) the set of variables appearing in tp (or in $\mathcal{GP}$, resp.).

Instance

A triple $t = (s, p, o)$ (or, resp., a set of triples, i.e., a graph $\mathcal{G}$) is an instance of a triple pattern $tp = (s_v, p_v, o_v)$ (or, resp., of a basic graph pattern $\mathcal{GP}$) if there exists a mapping $\mu{:}\mathcal{V} \cup \mathcal{RDFTerm} \rightarrow \mathcal{RDFTerm}$ which maps every element of $\mathcal{RDFTerm}$ to itself, such that $t = \mu(tp) = (\mu(s_v), \mu(p_v), \mu(o_v))$ (or, resp., and slightly simplifying notation, $\mathcal{G} = \mu(\mathcal{GP})$.

Terminological/Assertional Pattern

We refer to a *terminological -triple/-graph pattern* as one whose instance can only be a terminological triple or, resp., a set thereof. We denote a terminological collection pattern by *?x* p *(?e*^{1}, ..., *?e*^{n}*)* . where $p \in$ {`:intersectionOf`, `:oneOf`, `:unionOf`} and ?e^k is mapped by the object of a terminological collection triple $t_k^r = (o_k$, `rdf:first`, $e_k)$ as before. An assertional pattern is any pattern which is not terminological.

Inference Rule

We define an *inference rule* r as the pair ($\mathcal{A}nte$, $\mathcal{C}on$), where the antecedent $\mathcal{A}nte$ and the *consequent* $\mathcal{C}on$ are basic graph patterns such that $\mathcal{V}(\mathcal{C}on)$ and $\mathcal{V}(\mathcal{A}nte)$ are non-empty, $\mathcal{V}(\mathcal{C}on) \subseteq \mathcal{V}(\mathcal{A}nte)$ and $\mathcal{C}on$ does not contain blank nodes.[3] In this article, we will typically write inference rules as:

$$\mathcal{C}on \Rightarrow \mathcal{A}nte \qquad (1)$$

Rule Application and Closure

We define a *rule application* in terms of the immediate consequences of a rule r or a set of rules $\mathcal{R}$ on a graph $\mathcal{G}$ (here slightly abusing the notion of the immediate consequence operator in Logic Programming: cf. for example (Lloyd 1987)). That is, if r is a rule of the form (1), and $\mathcal{G}$ is a set of RDF triples, then:

$$T_r(\mathcal{G}) = \{\mu(\mathcal{C}on) \mid \exists\mu \text{ such that } \mu(\mathcal{A}nte) \subseteq G\}$$

and accordingly $T_\mathcal{R}(\mathcal{G}) = \bigcup_{r\in\mathcal{R}} T_r(\mathcal{G})$. Also, let $\mathcal{G}_{i+1} = \mathcal{G}_i \cup T_\mathcal{R}(\mathcal{G}_i)$ and $\mathcal{G}_0 = \mathcal{G}$; we now define the *exhaustive application* of the $T_\mathcal{R}$ operator on a graph $\mathcal{G}$ as being upto the least fixpoint (the smallest value for n) such that $\mathcal{G}_n = T_\mathcal{R}(\mathcal{G}_n)$. We call $\mathcal{G}_n$ the *closure* of $\mathcal{G}$ with respect to ruleset $\mathcal{R}$, denoted as $\mathcal{C}l_\mathcal{R}(\mathcal{G})$. Note that we may also use the intuitive notation $T_\mathcal{R}(\mathbb{KB})$, $\mathcal{C}l_\mathcal{R}(\mathbb{KB})$ as shorthand for the more cumbersome $T_\mathcal{R}(\bigcup_{\mathcal{W}'\in\mathbb{KB}}\mathcal{W}')$, $\mathcal{C}l_\mathcal{R}(\bigcup_{\mathcal{W}'\in\mathbb{KB}}\mathcal{W}')$ respectively.

Ground Triple/Graph

A ground triple or ground graph is one without existential variables.

Herbrand Interpretation

Briefly, a *Herbrand interpretation* of a graph $\mathcal{G}$ treats URI references, blank nodes, typed literals and plain literals analogously as denoting their own syntactic form. As such, a Herbrand interpretation represents a ground view of an RDF graph where blank nodes are treated as *Skolem names* instead of existential variables; i.e., blank nodes are seen to represent the entities that they assert the existence of, analogously to a URI reference. Henceforth, we view blank nodes as their Skolem equivalents (this also applies to blank nodes as mentioned in the above notation) and only treat the ground case of RDF graphs.

Let us elaborate in brief why this treatment of blank nodes as Skolem constants is sufficient for our purposes. In our scenario, we perform forward-chaining materialisation for query-answering and not "real" entailment checks between RDF graphs. This enables us to treat all blank nodes as Skolem names (Hayes 2004). It is well known that simple entailment checking of two RDF graphs (Hayes 2004)—i.e., checking whether an RDF graph $\mathcal{G}_1$ entails $\mathcal{G}_2$—can be done using the ground "skolemised" version of $\mathcal{G}_1$. That is $\mathcal{G}_1 \models \mathcal{G}_2$ iff $sk(\mathcal{G}_1) \models \mathcal{G}_2$. Likewise, given a set of inference rules $\mathcal{R}$, where we denote entailment with respect to $\mathcal{R}$ as $\models_{\mathcal{R}}$, it is again well known that such entailment can be reduced to simple entailment with prior computation of the inference closure with respect to $\mathcal{R}$. That is, $\mathcal{G}_1 \models_{\mathcal{R}} \mathcal{G}_2$ iff $\mathcal{C}l_{\mathcal{R}}(sk(\mathcal{G}_1)) \models \mathcal{G}_2$; cf. (Gutiérrez, Hurtado et al. 2004; Hayes 2004). In this article we focus on the actual computation of $\mathcal{C}l_{\mathcal{R}}(sk(\mathcal{G}_1))$ for a tailored ruleset $\mathcal{R}$ in between RDFS and OWL Full.

PRAGMATIC INFERENCING FOR THE WEB

In this section we discuss the inference rules which we use to approximate OWL semantics and are designed for forward-chaining reasoning over web data. We justify our selection of inferences to support in terms of observed characteristics and examples taken from the Web. We optimise by restricting our fragment of reasoning according to three imperatives: *computational feasibility* (CF) for scalability, reduced output statements (RO) to ease the burden on consumer applications and, finally, web-tolerance (WT) for avoiding undesirable inferences given noisy data and protecting publishers from unwanted, independent third-party contributions. In particular, we adhere to the following high-level restrictions:

- we are incomplete (CF, RO, WT) - Section 3.1;
- we deliberately ignore the explosive behaviour of classical inconsistency (CF, RO, WT) - Section 3.1;
- we follow a rule-based, finite, forward-chaining approach to OWL inference (CF) - Section 3.2;
- we do not invent new blank nodes (CF, RO, WT) - Section 3.2;
- we avoid inference of extended-axiomatic triples (RO) - Section 3.2;
- we focus on inference of non-terminological statements (CF) - Section 3.2;
- we do not consider `:sameAs` statements as applying to terminological data (CF, WT) - Section 3.2;
- we separate and store terminological data in-memory (CF) - Section 3.3;
- we support limited reasoning for non-standard use of the RDF(S) and OWL vocabularies (CF, RO, WT) - Section 3.3
- we ignore non-authoritative (third-party) terminological statements from our reasoning procedure to counter an explosion of inferred statements caused by hijacking ontology terms (RO, WT) - Section 3.4.

Infeasibility of Complete Web Reasoning

Reasoning over RDF data is enabled by the description of RDF terms using the RDFS and OWL standards; these standards have defined entailments determined by their semantics. The semantics of these standards differs in that RDFS entailment is defined in terms of "if" conditions (intensional semantics), and has a defined set of complete standard entailment rules (Hayes 2004). OWL semantics uses "iff" conditions (extensional semantics) without a complete set of standard entailment rules. RDFS entailment has been shown to be decidable and in P for the ground case (ter Horst 2005), whilst OWL Full entailment is known to be undecidable (Horrocks and Patel-Schneider 2004). Thus, the OWL standard includes two restricted fragments of OWL whose entailment is known to be decidable from work in description logics: (i) OWL DL whose worst-case entailment is in NEXPTIME (ii) OWL Lite whose worst-case entailment is in EXPTIME (Horrocks and Patel-Schneider 2004).

Although entailment for both fragments is known to be decidable, and even aside from their complexity, most OWL ontologies crawlable on the Web are in any case OWL Full: idealised assumptions made in OWL DL are violated by even very commonly used ontologies. For example, the popular Friend Of A Friend (FOAF) vocabulary (Brickley and Miller 2007) deliberately falls into OWL Full since (i) in the FOAF RDF vocabulary[4], `foaf:name` is defined as a sub-property of the core RDFS property `rdfs:label` and (ii) `foaf:mbox_sha1sum` is defined as both an `:InverseFunctionalProperty` and a `:DatatypeProperty`: both are disallowed by OWL DL (and, of course, OWL Lite). In (Bechhofer and Volz 2004), the authors identified and categorised OWL DL restrictions violated by a sample group of 201 OWL ontologies (all of which were found to be in OWL Full); these include incorrect or missing typing of classes and properties, complex object-properties (e.g., functional properties) declared to be transitive, inverse-functional datatype properties, etc. In (Wang, Parsia et al. 2006), a more extensive survey with nearly 1,300 ontologies was conducted: 924 were identified as being in OWL Full. Taking into account that most web ontologies are in OWL Full, and also the undecidability/computational-infeasiblity of OWL Full, one could conclude that complete reasoning on the Web is impractical. However, again for most web documents only categorisable as OWL Full, infringements are mainly syntactic and are rather innocuous with no real effect on decidability ((Wang, Parsia et al. 2006) showed that the majority of web documents surveyed were in the base expressivity for Description Logics after patching infringements). The main justification for the infeasibility of complete reasoning on the Web is inconsistency.

Consistency cannot be expected on the Web; for instance, a past web-crawl of ours revealed the following:

- `#timbl a foaf:Person; foaf:homepage <http://w3.org/> .`
- `#w3c a foaf:Organization; foaf:homepage <http://w3.org/> .`
- `foaf:homepage a :InverseFunctionalProperty .`
- `foaf:Organization :disjointWith foaf:Person .`

These triples together infer that Tim Berners-Lee is the same as the W3C and thus cause an inconsistency.[5] Aside from such examples which arise from misunderstanding of the FOAF vocabulary, there might be cases where different parties deliberately make contradictive statements; resolution of such contradictions could involve "choosing sides". In any case, the explosive nature of contradiction in classical logics suggests that it is not desirable within our web reasoning scenario.

Rule-Based Web Reasoning

As previously alluded to, there does not exist a standard entailment for OWL suitable to our web reasoning scenario. However, incomplete (wrt. OWL Full) rule-based inference (i.e., reasoning as performed by logic progamming or deductive database engines) may be considered to have greater potential for scale, following the arguments made in (Fensel and van Harmelen 2007) and may be considered to be more robust with respect to preventing explosive inferencing through inconsistencies. Several rule expressible non-standard OWL fragments; namely OWL-DLP (Grosof, Horrocks et al. 2004), OWL⁻ (de Bruijn 2008) (which is a slight extension of OWL-DLP), OWLPrime (Wu, Eadon et al. 2008), pD* (ter Horst 2005; ter Horst 2005), and Intensional OWL (de Bruijn 2008); have been defined in the literature and enable incomplete but sound RDFS and OWL Full inferences.

In (ter Horst 2005), pD* was introduced as a combination of RDFS entailment, datatype reasoning and a distilled version of OWL with rule-expressible intensional semantics: pD* entailment maintains the computational complexity of RDFS entailment, which is in NP in general and P for the ground case. Such improvement in complexity has obvious advantages in our web reasoning scenario; thus SAOR's approach to reasoning is inspired by the pD* fragment to cover large parts of OWL by positive inference rules which can be implemented in a forward-chaining engine.

Table 1 summarises the pD* ruleset. The rules are divided into D*-entailment rules and P-entailment rules. D*-entailment is essentially RDFS entailment (Hayes 2004) combined with some datatype reasoning. P-entailment is introduced in (ter Horst 2005) as a set of rules which applies to a property-related subset of OWL.

Given pD*, we make some amendments so as to align the ruleset with our requirements. Table 2 provides a full listing of our own modified ruleset,

Table 1. Ter-Horst rules from (ter Horst 2005) in Turtle-like syntax

pD*	rule	where
	D*-**entailment rules**	
lg	?x ?P ?l . ⇒ ?v ?P _:*bl* .	?l$\in \mathcal{L}$[a]

[a] `_:bl` is a *surrogate blank node* given by an injective function on the literal `?l`

which we compare against pD* in this section. Note that this table highlights characteristics of the rules which we will discuss in Section 3.3 and Section 3.4; for the moment we point out that **rule′** is used to indicate an amendment to the respective pD* rule. Please also note that we use the notation rulex* to refer to all rules with the prefix **rulex.**

pD* Rules Directly Supported

From the set of pD* rules, we directly support rules **rdfs2, rdfs9, rdfp2, rdfp4, rdfp7,** and **rdfp17.**

pD* Omissions: Extended-Axiomatic Statements

We avoid pD* rules which specifically produce what we term *extended-axiomatic* statements mandated by RDFS and OWL semantics. Firstly, we do not infer the set of pD* axiomatic triples, which are listed in (ter Horst 2005) for RDF(S) and OWL respectively; according to pD*, these are inferred for the empty graph. Secondly, we do not materialise membership assertions for `rdfs:Resource` which would hold for every URI and blank node in a graph. Thirdly, we do not ma-

Table 2. Supported rules in Turtle-style syntax. Terminological patterns are underlined whereas assertional patterns are not; further, rules are grouped according to arity of terminological/assertional patterns in the antecedent. The source of a terminological pattern instance must speak authoritatively for at lest one boldface variable binding for the rule to fire.

[a] $?C_i \in \{?C_1, ..., ?C_n\}$
[b] **rdfs3b** is a special case of **rdfs3c** with one A-Box pattern and thus falls under $\mathcal{R}1$.
[c] Only where **?p** is not an RDFS/OWL property used in any of our rules (see $\mathcal{P}_{SAOR}$, Section 3.3)

terialise reflexive `:sameAs` membership assertions, which again hold for every URI and blank node in a graph. We see such statements as inflationary and orthogonal to our aim of reduced output.

pD* Amendments: :sameAs Inferencing

From the previous set of omissions, we do not infer reflexive `:sameAs` statements. However, such reflexive statements are required by pD* rule **rdfp11.** We thus fragment the rule into **rdfp11′** and **rdfp11″** which allows for the same inferencing without such reflexive statements.

In a related issue, we wittingly do not allow `:sameAs` inferencing to interfere with terminological data: for example, we do not allow `:sameAs` inferencing to affect properties in the predicate position of a triple or classes in the object position of an `rdf:type` triple. In (Hogan, Harth et al. 2007) we showed that `:sameAs` inferencing through `:InverseFunctionalProperty` reasoning caused fallacious equalities to be asserted due to noisy web data. This is the primary motivation for us also omitting rules **rdfp9, rdfp10** and the reason why we place the restriction on `?p` for our rule **rdfp11″;** we do not want noisy equality inferences to be reflected in the terminological segment of our knowledge-base, nor to affect the class and property positions of membership assertions.

pD* Omissions: Terminological Inferences

From pD*, we also omit rules which infer only terminological statements: namely **rdf1, rdfs5, rdfs6, rdfs8, rdfs10, rdfs11, rdfs12, rdfs13, rdfp9, rdfp10, rdfp12*** and **rdfp13*.** As such, our use-case is query-answering over assertional data; we therefore focus in this article on materialising assertional data.

We have already motivated omission of inference through `:sameAs` rules **rdfp9** and **rdfp10.** Rules **rdf1, rdfs8, rdfs12** and **rdfs13** infer memberships of, or subclass/subproperty relations to, RDF(S) classes and properties; we are not interested in these primarily syntactic statements which are not directly used in our inference rules. Rules **rdfs6** and **rdfs10** infer reflexive memberships of `rdfs:subPropertyOf` and `rdfs:subClassOf` meta-properties which are used in our inference rules; clearly however, these reflexive statements will not lead to unique assertional inferences through related rules **rdfs7′ or rdfs9** respectively. Rules **rdfs5 and rdfs1**1 infer transitive memberships again of `rdfs:subPropertyOf` and `rdfs:subClassOf`; again however, exhaustive application of rules **rdfs7′ or rdfs9** respectively ensures that all possible assertional inferences are materialised without the need for the transitive rules. Rules **rdfp12c and rdfp13c** infer additional `:equivalentClass`/`:equivalentProperty` statements from `rdfs:subClassOf`/ `rdfs:subPropertyOf` statements where assertional inferences can instead be conducted through two applications each of rules **rdfs9** and **rdfs7′** respectively.

pD* Amendments: Direct Assertional Inferences

The observant reader may have noticed that we did not dismiss inferencing for rules **rdfp12a,rdfp12b/ rdfp13a,rdfp13b** which translate `:equivalentClass`/`:equivalentProperty` to `rdfs:subClassOf`/ `rdfs:subPropertyOf`. In pD*, these rules are required to support indirect assertional inferences through rules **rdfs9** and **rdfs7** respectively; we instead support assertional inferences directly from the `:equivalentProperty`/`:equivalentClass` statements using symmetric rules **rdfp12a′,rdfp12b′/ rdfp13a′,rdfp13b′.**

pD* Omissions: Existential Variables in Consequent

We avoid rules with existential variables in the consequent; such rules would require adaptation of the T_r operator so as to “invent” new blank nodes for each rule application, with undesireable effects for forward-chaining reasoning regarding termination. For example, like pD*, we only support inferences in one direction for `:someValuesFrom` and avoid a rule such as:

```
>    ?C :someValuesFrom ?D ; :onProperty ?P .
     ?x a ?C ⇒ ?x ?P _:b . _:b a ?D .
```

Exhaustive application of the rule to, for example, the following data (more generally where `?D` is a subclass of `?C`):

```
>    ?ex:Person rdfs:subClassOf [:someValues-
     From ex:Person ; :onProperty ex:mother
     .]
>    ? _:Tim a ex:Person .
```

would infer infinite triples of the type:

```
>    ? _:Tim ex:mother _:b0 .
>    ? _:b0 a ex:Person ; ex:mother _:b1 .
>    ? _:b1 a ex:Person ; ex:mother _:b2 .
...
```

In fact, this rule is listed in (ter Horst 2005) as **rdf-svx** which forms an extension of pD* entailment called *pD*sv*. This rule is omitted from pD* and from SAOR due to obvious side-effects on termination and complexity.

Unlike pD*, we also avoid inventing so called "surrogate" blank nodes for the purposes of representing a literal in intermediary inferencing steps (Rules **lg, gl, rdf2-D, rdfs1** in **RDFS/D*** entailment). Thus, we also do not support datatype reasoning (Rule **rdf2-D)** which involves the creation of surrogate blank nodes. Although surrogate blank nodes are created according to a direct mapping from a finite set of literals (and thus, do not prevent termination), we view "surrogate statements" as inflationary.

pD* Amendments: Relaxing Literal Restrictions

Since we do not support surrogate blank nodes as representing literals, we instead relax restrictions placed on pD* rules. In pD*, blank nodes are allowed in the predicate position of triples; however, the restriction on literals in the subject and predicate position still applies: literals are restricted from travelling to the subject or predicate position of a consequent (see *where column*, Table 1). Thus, surrogate blank nodes are required in pD* to represent literals in positions where they would otherwise not be allowed.

We take a different approach whereby we allow literals directly in the subject and predicate position for intermediate inferences. Following from this, we remove pD* literal restrictions on rules **rdfs3, rdfs7, rdfp1, rdfp3, rdfp6, rdfp8*, rdfp14b, rdfp16** for intermediate inferences and omit any inferred **non-RDF** statements from being written to the final output.

Additions to pD*

In addition to pD*, we also include some "class based entailment" from OWL, which we call C-entailment. We name such rules using the **rdfc* stem,** following the convention from **P-entailment.** We provide limited support for enumerated classes (**rdfc0**), union class descriptions (**rdfc1**), intersection class descriptions (**rdfc3***),[6] as well as limited cardinality constraints (**rdfc2, rdfc4*).**

pD* Amendments: Enforcing OWL Abstract Syntax Restrictions

Finally, unlike pD*, we enforce blank nodes as mandated by the OWL Abstract Syntax (Patel-Schneider and Horrocks 2004), wherein certain abstract syntax constructs (most importantly in our case: *unionOf(description$_1$...*

description$_n$), intersectionOf(description$_1$... description$_n$), oneOf(iID$_1$...iID$_n$), restriction(ID allValuesFrom(range)), restriction(ID someValuesFrom(required)), restriction(ID value(value)), restriction(ID maxCardinality(max)), restriction(ID minCardinality(min)), restriction(ID cardinality(card)) and *SEQ item$_1$...item$_n$)* are strictly mapped to RDF triples with blank nodes enforced for certain positions: such mapping is necessitated by the idiosyncrasies of representing OWL in RDF. Although the use of URIs in such circumstances is allowed by RDF, we enforce the use of blank nodes for terminological patterns in our ruleset; to justify, let us look at the following problematic example of OWL triples taken from two sources:

```
>    SOURCE <ex:>
>    ex:Person :onProperty ex:parents ; :som-
     eValuesFrom ex:Person .
>    SOURCE <ex2:>
>    ex:Person :allValuesFrom ex2:Human .
```

According to the abstract syntax mapping, neither of the restrictions should be identified by a URI (if blank nodes were used instead of `ex:Person` as mandated by the abstract syntax, such a problem could not occur as each web-graph is given a unique set of blank nodes). If we consider the RDF-merge of the two graphs, we will be unable to distinguish which restriction the `:onProperty` value applies to. As above, allowing URIs in these positions would enable "syntactic interference" between data sources. Thus, in our ruleset, we always enforce blank-nodes as mandated by the OWL abstract syntax; this specifically applies to pD* rules **rdfp14*, rdfp15′** and **rdfp16′** and to all of our **C-entailment** rules **rdfc*.** We denote the restrictions in the where column of Table 2. Indeed, in our treatment of terminological collection statements, we enforced blank nodes in the subject position of `rdf:first`/`rdf:rest` membership assertions, as well as blank nodes in the object position of non-terminating `rdf:rest` statements; these are analogously part of the OWL abstract syntax restrictions.

Separation of T-Box from A-Box

Aside from the differences already introduced, our primary divergence from the pD* fragment and traditional rule-based approaches is that we separate terminological data from assertional data according to their use of the RDF(S) and OWL vocabulary; these are commonly known as the "T-Box" and "A-Box" respectively (loosely borrowing Description Logics terminology). In particular, we require a separation of T-Box data as part of a core optimisation of our approach; we wish to perform a once-off load of T-Box data from our input knowledge-base into main memory.

Let $\mathcal{P}_{SAOR}$ and $\mathcal{C}_{SAOR}$ and be, resp., the exact set of RDF(S)/OWL meta-properties and -classes used in our inference rules; viz. $\mathcal{P}_{SAOR}$ = { `rdfs:domain`, `rdfs:range`, `rdfs:subClassOf`, `rdfs:subPropertyOf`, `:allValuesFrom`, `:cardinality`, `:equivalentClass`, `:equivalentProperty`, `:hasValue`, `:intersectionOf`, `:inverseOf`, `:maxCardinality`, `:minCardinality`, `:oneOf`, `:onProperty`, `:sameAs`, `:someValuesFrom`, `:unionOf` } & $\mathcal{C}_{SAOR}$ = { `:FunctionalProperty`, `:InverseFunctionalProperty`, `:SymmetricProperty`, `:TransitiveProperty` }; our T-Box is a set of terminological triples restricted to only include membership assertions for $\mathcal{P}_{SAOR}$ and $\mathcal{C}_{SAOR}$ and the set of terminological collection statements. Table 2 identifies T-Box patterns by underlining. Statements from the input knowledge-base that match these patterns are all of the T-Box statements we consider in our reasoning process: inferred statements or statements that do not match one of these patterns are not considered being part of the T-Box, but are treated purely as assertional. We now define our T-Box:

Definition 1 (T-Box) *Let $\mathcal{T}_{\mathcal{G}}$ be the union of all graph pattern instances from a graph $\mathcal{G}$ for a* *terminological (underlined) graph pattern in Table 2; i.e., $\mathcal{T}_{\mathcal{G}}$ is itself a graph. We call $\mathcal{T}_{\mathcal{G}}$ the T-Box of $\mathcal{G}$.*

Also, let $\mathcal{P}^{domP}_{SAOR}$ = {`rdfs:domain`, `rdfs:range`, `rdfs:subPropertyOf`, `:equivalentProperty`, `:inverseOf` } and $\mathcal{P}^{ranP}_{SAOR}$ = { `rdfs:subPropertyOf`, `:equivalentProperty`, `:inverseOf`, `:onProperty`}, We call ϕ a property in T-Box $\mathcal{T}$ if there exists a triple $t \in \mathcal{T}$ where

- $s = \phi$ and $p \in \mathcal{P}^{domP}_{SAOR}$
- $p \in \mathcal{P}^{ranP}_{SAOR}$ and $o = \phi$
- $s = \phi$, $p =$ `rdf:type` and $o \in \mathcal{C}_{SAOR}$

Similarly, let $\mathcal{P}^{domC}_{SAOR}$ = {`rdfs:subClassOf`, `:allValuesFrom`, `:cardinality`, `:equivalentClass`, `:hasValue`, `:intersectionOf`, `:maxCardinality`, `:minCardinality`, `:oneOf`, `:onProperty`, `:someValuesFrom`, `:unionOf`} and $\mathcal{P}^{ranC}_{SAOR}$ = {`rdfs:domain`, `rdfs:range`, `rdfs:subClassOf`, `rdf:first`, `:allValuesFrom`, `:equivalentClass`, `:someValuesFrom`}. We call $\mathcal{X}$ a class in T-Box $\mathcal{T}$ if there exists a triple $t \in \mathcal{T}$ where

- $p \in \mathcal{P}^{domC}_{SAOR}$ *and* $s = \mathcal{X}$
- $p \in \mathcal{P}^{ranC}_{SAOR}$ *and* $o = \mathcal{X}$

We define the signature of a T-Box $\mathcal{T}$ to be the set of all properties and classes in $\mathcal{T}$ as above, which we denote by $sig(\mathcal{T})$.

For our knowledge-base $\mathbb{KB}$, we define our T-Box $\mathbb{T}$ as the set of all pairs $(\mathcal{T}_{\mathcal{W}'}, c)$ where $(\mathcal{W}', c) \in \mathbb{KB}$, and $\mathcal{T}_{\mathcal{W}'} \neq \emptyset$. Again, we may use the intuitive notation $\mathcal{T}_{\mathcal{W}'} \in \mathbb{T}$. We define our A-Box $\mathbb{A}$ as containing all of the statements in $\mathbb{KB}$, including $\mathbb{T}$ and the set of class and property membership assertions possibly using identifiers in $\mathcal{P}_{SAOR} \cup \mathcal{C}_{SAOR}$; i.e., unlike description logics, our $\mathbb{A}$ is synonymous with our $\mathbb{KB}$. We use the term A-Box to distinguish data that are stored on-disk (which includes T-Box data also stored in memory).

We now define our notion of a $\mathcal{T}$-split inference rule, whereby part of the antecedent is a basic graph pattern strictly instantiated by a static T-Box $\mathcal{T}$.

Definition 2 ($\mathcal{T}$-split inference rule) *We define a $\mathcal{T}$-split inference rule r as the triple $(\mathcal{A}nte_{\mathcal{T}}, \mathcal{A}nte_{\mathcal{G}}, \mathcal{C}on)$, where $\mathcal{A}nte_{\mathcal{T}}$ is a basic graph pattern matched by a static T-Box $\mathcal{T}$ and $\mathcal{A}nte_{\mathcal{G}}$ is matched by data in the graph $\mathcal{G}$, $\mathcal{C}on$ does not contain blank nodes, $\mathcal{V}(\mathcal{C}on) \neq \emptyset$, $\mathcal{V}(\mathcal{C}on) \subseteq \mathcal{V}(\mathcal{A}nte_{\mathcal{T}}) \cup \mathcal{V}(\mathcal{A}nte_{\mathcal{G}})$; also, if both $\mathcal{A}nte_{\mathcal{T}}$ and $\mathcal{A}nte_{\mathcal{G}}$ are non-empty, then $\mathcal{V}(\mathcal{A}nte_{\mathcal{T}}) \cap \mathcal{V}(\mathcal{A}nte_{\mathcal{G}}) \neq \emptyset$.*

We generally write $(\mathcal{A}nte_{\mathcal{T}}, \mathcal{A}nte_{\mathcal{G}}, \mathcal{C}on)$ as $\underline{\mathcal{A}nte_{\mathcal{T}}}\mathcal{A}nte_{\mathcal{G}} \Rightarrow \mathcal{C}on$. We call $\mathcal{A}nte_{\mathcal{T}}$ the terminological or T-Box antecedent pattern and $\mathcal{A}nte_{\mathcal{G}}$ the assertional or A-Box pattern.

Definition 3 (Rule-sets $\mathcal{R}_{\mathcal{T}}$, $\mathcal{R}_{\mathcal{TG}}$, $\mathcal{R}_{\mathcal{G}}$) *We define $\mathcal{R}_{\mathcal{T}}$ as the set of $\mathcal{T}$-split rules for which $\mathcal{A}nte_{\mathcal{T}} \neq \emptyset$ and $\mathcal{A}nte_{\mathcal{G}} = \emptyset$. We define $\mathcal{R}_{\mathcal{TG}}$ as the set of $\mathcal{T}$-split rules for which $\mathcal{A}nte_{\mathcal{T}} \neq \emptyset$ and $\mathcal{A}nte_{\mathcal{G}} \neq \emptyset$. We define $\mathcal{R}_{\mathcal{G}}$ as the set of $\mathcal{T}$-split rules for which $\mathcal{A}nte_{\mathcal{T}} \neq \emptyset$ and $\mathcal{A}nte_{\mathcal{G}} \neq \emptyset$.*

In Table 2, we categorise the $\mathcal{T}$-split rules into four rulesets: $\mathcal{R}0 \subset \mathcal{R}_{\mathcal{T}}$; $\mathcal{R}1 \subset \mathcal{R}_{\mathcal{TG}}$ where $|\mathcal{A}nte_{\mathcal{G}}| = 1$; $\mathcal{R}2 \subset \mathcal{R}_{\mathcal{TG}}$ where $|\mathcal{A}nte_{\mathcal{G}}| > 1$ and $\mathcal{R}0 \subset \mathcal{R}_{\mathcal{G}}$.

We now introduce the notion of a *$\mathcal{T}$-split inference* rule application for a graph $\mathcal{G}$ w.r.t. a *T-Box $\mathcal{T}$:*

Definition 4 ($\mathcal{T}$-split inference rule application) *We define a $\mathcal{T}$-split rule application to be $\mathcal{T}_r(\mathcal{T}, \mathcal{G})$ for $r = (\mathcal{A}nte_{\mathcal{T}}, \mathcal{A}nte_{\mathcal{G}}, \mathcal{C}on)$ as follows:*

$T_r(\mathcal{T}, \mathcal{G}) = \{\mu(\mathcal{C}on) | \exists\mu$ such that $\mu(\mathcal{A}nte_{\mathcal{T}}) \subseteq T$ and $\mu(\mathcal{A}nte_{\mathcal{G}}) \subseteq G\}$

Again, $\mathcal{T}_{\mathcal{R}}(\mathcal{T}, \mathcal{G}) = \bigcup_{r \in \mathcal{R}} \mathcal{T}_r(\mathcal{T}, \mathcal{G})$; also, given $\mathcal{T}$ as static, the exhaustive application of the $\mathcal{T}_{\mathcal{R}}(\mathcal{T}, \mathcal{G})$ up to the least fixpoint is called the *$\mathcal{T}$-split* closure of $\mathcal{G}$, denoted as $\mathcal{C}l_{\mathcal{R}}(\mathcal{T}, \mathcal{G})$. Again we use abbreviations such as $\mathcal{T}_{\mathcal{R}}(\mathbb{T}, \mathbb{KB})$ and $\mathcal{Cl}_{\mathcal{R}}(\mathbb{T}, \mathbb{KB})$, where $\mathbb{KB}$ should be interpreted as $\bigcup_{\mathcal{W}' \in \mathbb{KB}} \mathcal{W}'$ and $\mathbb{T}$ as $\bigcup_{\mathcal{T}_{\mathcal{W}'} \in \mathbb{T}} \mathcal{T}_{\mathcal{W}'}$.

Please note that since we enforce blank nodes in all positions mandated by the OWL abstract syntax for our rules, each instance of a given graph pattern $\mathcal{A}nte_{\mathcal{T}}$ can only contain triples from one web-graph $\mathcal{W}'$ where $\mathcal{T}_{\mathcal{W}'} \in \mathbb{T}$. Let $\mathcal{V}_{\mathcal{B}}(\mathcal{GP})$ be the set of all variables in a graph pattern $\mathcal{GP}$ which we restrict to only be instantiated by a blank node according to the abstract syntax. For all $\mathcal{A}nte_{\mathcal{T}}$ in our rules where $|\mathcal{A}nte_{\mathcal{T}}| > 1$ let $\mathcal{A}nte_{\overline{\mathcal{T}}}$ be any proper non-empty subset of $\mathcal{A}nte_{\mathcal{T}}$; we can then say that $\mathcal{V}_{\mathcal{B}}(\mathcal{A}nte_{\overline{\mathcal{T}}}) \cap \mathcal{V}_{\mathcal{B}}(\mathcal{A}nte_{\mathcal{T}} \setminus \mathcal{A}nte_{\overline{\mathcal{T}}}) \neq \emptyset$. In other words, since for every rule either (i) $\mathcal{A}nte_{\mathcal{T}} = \emptyset$; or (ii) $\mathcal{A}nte_{\mathcal{T}}$ consists of a single triple pattern; or (iii) no sub-pattern of any $\mathcal{A}nte_{\mathcal{T}}$ in our rules contains a unique set of blank-node enforced variables; then a given instance of $\mathcal{A}nte_{\mathcal{T}}$ can only contain triples from one web-graph with unique blank nodes as is enforced by our knowledge-base. For our ruleset, we can then say that $T_R(\mathbb{T}, \mathbb{KB}) = T_R(\bigcup_{\mathcal{T}_{\mathcal{W}'} \in \mathbb{T}} \mathcal{T}_{\mathcal{W}'}, \mathbb{KB}) = \bigcup_{\mathcal{T}_{\mathcal{W}'} \in \mathbb{T}} T_R(\mathcal{T}_{\mathcal{W}'}, \mathbb{KB})$. In other words, one web-graph cannot re-use structural statements in another web-graph to instantiate a T-Box pattern in our rule; this has bearing on our notion of authoritative reasoning which will be highlighted at the end of Section 3.4.

Further, a separate static T-Box within which inferences are not reflected has implications upon the completeness of reasoning w.r.t. the presented ruleset. Although, as presented in Section 3.2, we do not infer terminological statements and thus can support most inferences directly from our static T-Box, SAOR still does not fully support meta-modelling (Motik 2007): by separating the T-Box segment of the knowledge-base, we do not support all possible entailments from the simultaneous description of both a class (or property) and an individual. In other words, we do not fully support inferencing for meta-classes or meta-properties defined outside of the RDF(S)/OWL specification.

However, we do provide limited reasoning support for meta-modelling in the spirit of "punning" by conceptually separating the individual-, class- or property-meanings of a resource; c.f. (Grau, Horrocks et al. 2006). More precisely, during reasoning we not only store the T-Box data in memory, but also store the data on-disk in the A-Box. Thus, we perform punning in one direction: viewing class and property descriptions which form our T-Box also as individuals in our A-Box. Interestingly, although we do not support terminological reasoning directly, we can through our limited punning perform reasoning for terminological data based on the RDFS descriptions provided for the RDFS and OWL specifications. For example, we would infer the following by storing the three input statements in both the T-Box and the A-Box:

```
> rdfs:subClassOf rdfs:domain rdfs:Class;
  rdfs:range rdfs:Class .
> ex:Class1 rdfs:subClassOf ex:Class2 . ⇒
> ex:Class1 a rdfs :Class .
  ex:Class2 a rdfs:Class .
```

However, again our support for meta-modelling is limited; SAOR does not fully support so-called "non-standard usage" of RDF(S) and OWL: the use of properties and classes which make up the RDF(S) and OWL vocabularies in locations where they have not been intended, cf. (de Bruijn and Heymans 2007; Muñoz, Pérez et al. 2007). We adapt and refine the definition of non-standard vocabulary use for our purposes according to the parts of the RDF(S) and OWL vocabularies relevant for our inference ruleset:

Definition 5 (Non-standard Vocabulary Usage) *An RDF triple t has non-standard vocabulary usage for our ruleset if one of the following conditions holds:*

- a property in $\mathcal{P}_{SAOR}$ appears in a position different from the predicate position; or

- a class in $\mathcal{C}_{SAOR}$ appears in a position different from the object position of an `rdf:type` triple.

Continuing, we now introduce the following example wherein the first input statement is a case of non-standard usage with `rdfs:subClassOf` $\in \mathcal{P}_{SAOR}$ in the object position:[7]

> `ex:subClassOf rdfs:subPropertyOf rdfs:subClassOf .`
> `ex:Class1 ex:subClassOf ex:Class2 .` ⇒
> `ex:Class1 rdfs:subClassOf ex:Class2 .`

We can see that SAOR provides inference through `rdfs:subPropertyOf` as per usual; however, the inferred triple will not be reflected in the T-Box, thus we are incomplete and will not translate members of `ex:Class1` into `ex:Class2`. As such, non-standard usage may result in T-Box statements being produced which, according to our limited form of punning, will not be reflected in the T-Box and will lead to incomplete inference.

Indeed, there may be good reason for not fully supporting non-standard usage of the ontology vocabulary: non-standard use could have unpredictable results even under our simple rule-based entailment if we were to fully support meta-modelling. One may consider a finite combination of only four non-standard triples that, upon naive reasoning, would explode all web resources R by inferring $|R|^3$ triples, namely:

> `rdfs:subClassOf rdfs:subPropertyOf rdfs:Resource .`
> `rdfs:subClassOf rdfs:subPropertyOf rdfs:subPropertyOf .`
> `rdf:type rdfs:subPropertyOf rdfs:subClassOf .`
> `rdfs:subClassOf rdf:type :SymmetricProperty .`

The exhaustive application of standard RDFS inference rules plus inference rules for property symmetry together with the inference for class membership in `rdfs:Resource` for all collected resources in typical rulesets such as pD* lead to inference of any possible triple (r_1, r_2, r_3) for arbitrary $r_1, r_2, r_3 \in R$. Thus, although by maintaining a separate static T-Box we are incomplete w.r.t non-standard usage, we show that complete support of such usage of the RDFS/OWL vocabularies is undesirable for the Web.[8]

Authoritative Reasoning against Ontology Hijacking

During initial evaluation of a system which implements reasoning upon the above ruleset, we encountered a behaviour which we term "ontology hijacking", symptomised by a perplexing explosion of materialised statements. For example, we noticed that for a single `foaf:Person` membership assertion, SAOR inferred in the order of hundreds of materialised statements as opposed to the expected six. Such an explosion of statements is orthogonal to the aim of reduced materialised statements we have outlined for SAOR; thus, SAOR is designed to annul the diagnosed problem of ontology hijacking through anaylsis of the authority of web sources for T-Box data. Before formally defining ontology hijacking and our proposed solution, let us give some preliminary definitions:

Definition 6 (Authoritative Source) *A web-graph $\mathcal{W}$ from source (context) c speaks authoritatively about an RDF term n iff:*

- $n \in \mathcal{B}$; or
- $n \in \mathcal{U}$ and c coincides with, or is redirected to by, the namespace[9] of n.

Firstly, all graphs are authoritative for blank nodes defined in that graph (remember that according to the definition of our knowledge-base, all blank nodes are unique to a given graph). Secondly, we support namespace redirects so as to conform to best practices as currently adopted by web ontology publishers.[10]

For example, as taken from the Web:

- Source `http://usefulinc.com/ns/doap` is authoritative for all classes and properties which are within the `http://usefulinc.com/ns/doap` namespace; e.g., `http://usefulinc.com/ns/doap#Project`.
- Source `http://xmlns.com/foaf/spec/` is authoritative for all classes and properties which are within the `http://xmlns.com/foaf/0.1/` namespace; e.g., `http://xmlns.com/foaf/0.1/knows`; since the property `http://xmlns.com/foaf/0.1/knows` redirects to `http://xmlns.com/foaf/spec/`.

We consider the authority of sources speaking about classes and properties in our T-Box to counter-act ontology hijacking; ontology hijacking is the assertion of a set of non-authoritative T-Box statements such that could satisfy the terminological pattern of a rule in $\mathcal{R}_{\mathcal{TG}}$ (i.e., those rules with at least one terminological and at least one assertional triple pattern in the antecedent). Such third-party sources can then cause arbitrary inferences over membership assertions of classes or properties (contained in the A-Box) for which they speak non-authoritatively. We can say that only rules in $\mathcal{R}_{\mathcal{TG}}$ are relevant to ontology hijacking since: (i) inferencing on $\mathcal{R}_{\mathcal{G}}$, which does not contain any T-Box patterns, cannot be affected by non-authoritative T-Box statements; and (ii) the $\mathcal{R}_{\mathcal{T}}$ ruleset does not contain any assertional antecedent patterns and therefore, cannot hijack assertional data (i.e., in our scenario, the `:oneOf` construct can be viewed as directly asserting memberships, and is unable, according to our limited support, to redefine sets of individuals). We now define ontology hijacking:

Definition 7 (Ontology Hijacking) *Let $\mathcal{T}_{\mathcal{W}}$ be the T-Box extracted from a web-graph $\mathcal{W}$ and let $\widehat{sig}(\mathcal{W})$ be the set of classes and properties for which $\mathcal{W}$ speaks authoritatively; then if $\mathcal{C}l_{\mathcal{R}_{\mathcal{TG}}}(\mathcal{T}_{\mathcal{W}}, \mathcal{G}) \neq \mathcal{G}$ for any $\mathcal{G}$ not mentioning any element of $\widehat{sig}(\mathcal{W})$, we say that web-graph $\mathcal{W}$ is performing ontology hijacking.*

In other words, ontology hijacking is the contribution of statements about classes or properties in a non-authoritative source such that reasoning on members of those classes or properties is affected. One particular method of ontology hijacking is defining new super-classes or properties of third-party classes or properties. As a concrete example, if one were to publish today a description of a property in an ontology (in a location non-authoritative for `foaf:` but authoritative for `my:`), `my:name`, within which the following was stated: `foaf:name rdfs:subPropertyOf my:name .`, that person would be hijacking the `foaf:name` property and effecting the translation of all `foaf:name` statements in the web knowledge-base into `my:name` statements as well. However, if the statement were instead `my:name rdfs:subPropertyOf foaf:name .`, this would not constitute a case of ontology hijacking but would be a valid example of translating from a local authoritative property into an external non-authoritative property.

Ontology hijacking is problematic in that it vastly increases the amount of statements that are materialised and can potentially harm inferencing on data contributed by other parties. With respect to materialisation, the former issue becomes prominent: members of classes/properties from popular/core ontologies get translated into a plethora of conceptual models described in obscure ontologies; we quantify the problem in Section 5. However, taking precautions against harmful ontology hijacking is growing more and more important as the Semantic Web features more and more attention; motivation for spamming and other malicious activity propagates amongst certain parties with ontology hijacking being a prospective avenue. With this in mind, we assign sole responsibility for classes and properties and reasoning upon their members to those who maintain the authoritative specification.

Related to the idea of ontology hijacking is the idea of "non-conservative extension" described in the Description Logics literature: cf. (Ghilardi, Lutz et al. 2006; Lutz, Walther et al. 2007; Jiménez-Ruiz, Grau et al. 2008). However, the notion of a "conservative extension" was defined with a slightly different objective in mind: according to the notion of deductively conservative extensions, a graph $\mathcal{G}_a$ is only considered malicious towards $\mathcal{G}_b$ if it causes additional inferences with respect to the intersection of the signature of the original $\mathcal{G}_b$ with the newly inferred statements. Returning to the former `my:name` example from above, defining a super-property of `foaf:name` would still constitute a conservative extension: the closure without the non-authoritative `foaf:name rdfs:subPropertyOf my:name .` statement is the same as the closure with the statement after all of the `my:name` membership assertions are removed. However, further stating that `my:name a :InverseFunctionalProperty.` would not satisfy a model conservative extension since members of `my:name` might then cause equalities in other remote ontologies as side-effects, independent from the newly defined signature. Summarising, we can state that every non-conservative extension (with respect to our notion of deductive closure) constitutes a case of ontology hijacking, but not vice versa; non-conservative extension can be considered "harmful" hijacking whereas the remainder of ontology hijacking cases can be considered "inflationary".

To negate ontology hijacking, we only allow inferences through *authoritative rule applications*, which we now define:

Definition 8 (Authoritative Rule Application) *Again let $\widehat{sig}(\mathcal{W})$ be the set of classes and properties for which $\mathcal{W}$ speaks authoritatively and let $\mathcal{T}_{\mathcal{W}}$ be the T-Box of $\mathcal{W}$. We define an authoritative rule application for a graph $\mathcal{G}$ w.r.t. the T-Box $\mathcal{T}_{\mathcal{W}}$ to be a $\mathcal{T}$-split rule application $\mathcal{T}_r(\mathcal{T}_{\mathcal{W}}, \mathcal{G})$ where additionally, if both $\mathcal{A}nte_{\mathcal{T}}$ and $\mathcal{A}nte_{\mathcal{G}}$ are non-empty ($r \in \mathcal{R}_{\mathcal{TG}}$), then for the mapping μ of $\mathcal{T}_r(\mathcal{T}_{\mathcal{W}}, \mathcal{G})$ there must exist a variable $v \in (\mathcal{V}(\mathcal{A}nte_{\mathcal{T}}) \cap \mathcal{V}(\mathcal{A}nte_{\mathcal{G}}))$ such that $\mu(v) \in \widehat{sig}(\mathcal{W})$. We denote an authoritative rule application by $\mathcal{T}_{\hat{r}}(\mathcal{T}_{\mathcal{W}}, \mathcal{G})$.*

In other words, an authoritative rule application will only occur if the rule consists of only assertional patterns ($\mathcal{R}_{\mathcal{G}}$); or the rules consists of only terminological patterns ($\mathcal{R}_{\mathcal{T}}$); or if in application of the rule, the terminological pattern instance is from a web-graph authoritative for at least one class or property in the assertional pattern instance. The $T_{\hat{R}}$ operator follows naturally as before for a set of authoritative rules $\hat{\mathcal{R}}$, as does the notion of authoritative closure which we denote by $Cl_{\hat{R}}(\mathcal{T}, \mathcal{W})$. We may also refer to, e.g., $T_{\hat{R}}(\mathbb{T}, \mathbb{KB})$ and $Cl_{\hat{R}}(\mathbb{T}, \mathbb{KB})$ as before for a $\mathcal{T}$-split rule application.

Table 2 identifies the authoritative restrictions we place on our rules wherein the underlined T-Box pattern is matched by a set of triples from a web-graph $\mathcal{W}$ iff $\mathcal{W}$ speaks authoritatively for at least one element matching a boldface variable in Table 2; i.e., again, for each rule, at least one of the classes or properties matched by the A-Box pattern of the antecedent must be authoritatively spoken for by an instance of the T-Box pattern. These restrictions only apply to $\mathcal{R}1$ and $\mathcal{R}2$ (which are both a subset of $\mathcal{R}_{\mathcal{TG}}$). Please note that, for example in rule **rdfp14b′** where there are no boldface variables, the variables enforced to be instantied by blank nodes will always be authoritatively spoken for: a web-graph is always authoritative for its blank nodes.

We now make the following proposition relating to the prevention of ontology-hijacking through authoritative rule application:

Proposition 1 *Given a T-Box $\mathcal{T}_{\mathcal{W}}$ extracted from a web-graph $\mathcal{W}$ and any graph $\mathcal{G}$ not mentioning any element of $\widehat{sig}(\mathcal{W})$, then $Cl_{\widehat{\mathcal{R}_{\mathcal{TG}}}}(\mathcal{T}_{\mathcal{W}}, \mathcal{G}) = \mathcal{G}$.*

Proof: Informally, our proposition is that the authoritative closure of a graph $\mathcal{G}$ w.r.t. some T-Box $\mathcal{T}_{\mathcal{W}}$ will not contain any inferences which constitute ontology hijacking, defined in terms of ruleset $\mathcal{R}_{\mathcal{TG}}$.

Firstly, from Definition 3, for each rule $r \in \mathcal{R}_{\mathcal{TG}}$, $\mathcal{A}nte_{\mathcal{T}} \neq \emptyset$ and $\mathcal{A}nte_{\mathcal{G}} \neq \emptyset$. Therefore, from Definitions 4 & 8, for an authoritative rule application to occur for any such r, there must exist both (i) a mapping μ such that $\mu(\mathcal{A}nte_{\mathcal{T}}) \subseteq \mathcal{T}_{\mathcal{W}}$ and $\mu(\mathcal{A}nte_{\mathcal{G}}) \subseteq \mathcal{G}$; and (ii) a variable $v \in ((\mathcal{A}nte_{\mathcal{T}})(\mathcal{A}nte_{\mathcal{G}}))$ such that $\mu(v) \in \widehat{sig}(\mathcal{W})$. However, since $\mathcal{G}$ does not mention any element of $\widehat{sig}(\mathcal{W})$, then there is no such mapping μ where $\mu(v) \in \widehat{sig}(\mathcal{W})$ for $v \in \mathcal{V}(\mathcal{A}nte_{\mathcal{G}})$, and $\mu(\mathcal{A}nte_{\mathcal{G}}) \subseteq \mathcal{G}$. Hence, for $r \in \mathcal{R}_{\mathcal{TG}}$, no such application $\mathcal{T}_{\hat{r}}(\mathcal{T}_{\mathcal{W}}, \mathcal{G})$ will occur; it then follows that $\mathcal{T}_{\widehat{\mathcal{R}_{\mathcal{TG}}}}(\mathcal{T}_{\mathcal{W}}, \mathcal{G}) = \emptyset$ and $Cl_{\widehat{\mathcal{R}_{\mathcal{TG}}}}(\mathcal{T}_{\mathcal{W}}, \mathcal{G}) = \mathcal{G}$. □

The above proposition and proof holds for a given web-graph $\mathcal{W}$; however, given a set of web-graphs where an instance of $\mathcal{A}nte_{\mathcal{T}}$ can consist of triples from more that one graph, it is possible for ontology hijacking to occur whereby some triples in the instance come from a non-authoritative graph and some from an authoritative graph. To illustrate we refer to the following example, wherein (and without enforcing abstract syntax blank nodes) the second source could cause ontology hijacking by interfering with the authoritative definition of the class restriction in the first source as follows:

```
>   RULE (adapted so that ?C need not be a
    blank node)
>   ?C :allValuesFrom ?D ; :onProperty ?P .
    ?x a ?C ; ?P ?y . ⇒ ?y a ?D .
>   SOURCE <ex:>
>   ex:Person :onProperty ex:parent.
>   SOURCE <ex2:>
>   ex:Person :allValuesFrom ex2:Human
>   ASSERTIONAL
>   _:Jim a ex:Person ; ex:parent _:Jill .
>   ⇒
>   _:Jill a ex2:Human .
```

Here, the above inference is authoritative according to our definition since the instance of $\mathcal{A}nte_{\mathcal{T}}$ (specifically the first statement from `source <ex:>`) speaks authoritatively for a class/property in the assertional data; however, the statement from the `<ex2:>` source is causing inferences on assertional data not containing a class or property for which `<ex2:>` is authoritative.

As previously discussed, for our ruleset, we enforce the OWL abstract syntax and thus we enforce that $\mu(\mathcal{A}nte_{\mathcal{T}}) \subseteq \mathcal{T}_{\mathcal{W}'}$ where $\mathcal{T}_{\mathcal{W}'} \in \mathbb{T}$. However, where this condition does not hold (i.e., an instance of $\mathcal{A}nte_{\mathcal{T}}$ can comprise of data from more than one graph), then an authoritative rule application should only occur if each web-graph contributing to an instance of $\mathcal{A}nte_{\mathcal{T}}$ speaks authoritatively for at least one class/property in the $\mathcal{A}nte_{\mathcal{G}}$ instance.

REASONING ALGORITHM

In the following we first present observations on web data that influenced the design of the SAOR algorithm, then give an overview of the algorithm, and next discuss details of how we handle T-Box information, perform statement-wise reasoning, and deal with equality for individuals.

Characteristics of Web Data

Our algorithm is intended to operate over a web knowledge-base as retrieved by means of a web crawl; therefore, the design of our algorithm is motivated by observations on our web dataset:

1. Reasoning accesses a large slice of data in the index: we found that approximately 61% of statements in the 147m dataset and 90% in the 1.1b dataset produced inferred statements through authoritative reasoning.
2. Relative to assertional data, the volume of terminological data on the Web is small: < 0.9% of the statements in the 1.1b dataset and <1.7% of statements in the 147m dataset were classifiable as SAOR T-Box statements.[11]
3. The T-Box is the most frequently accessed segment of the knowledge-base for reason-

ing: although relatively small, all but the rules in $\mathcal{R}3$ require access to T-Box information.

Following from the first observation, we employ a file-scan batch-processing approach so as to enable sequential access over the data and avoid disk-lookups and dynamic data structures which would not perform well given high disk latency; also we avoid probing the same statements repeatedly for different rules at the low cost of scanning a given percentage of statements not useful for reasoning.

Following from the second and third observations, we optimise by placing T-Box data in a separate data structure accessible by the reasoning engine. Currently, we hold all T-Box data in-memory, but the algorithm can be generalised to provide for a caching on-disk structure or a distributed in-memory structure as needs require.[12]

To be able to scale, we try to minimise the amount of main memory needed, given that main memory is relatively expensive and that disk-based algorithms are thus more economical (Kunkle and Cooperman 2008). Given high disk latency, we avoid using random-access on-disk data structures. In our previous work a disk-based updateable random-access data structure (a B+-Tree) proved to be the bottleneck for the reasoning due to a high volume of inserts, leading to frequent index reorganisations and hence inadequate performance. As a result, our algorithms are now build upon two disk-based primitives known to scale: file scanning and sorting.

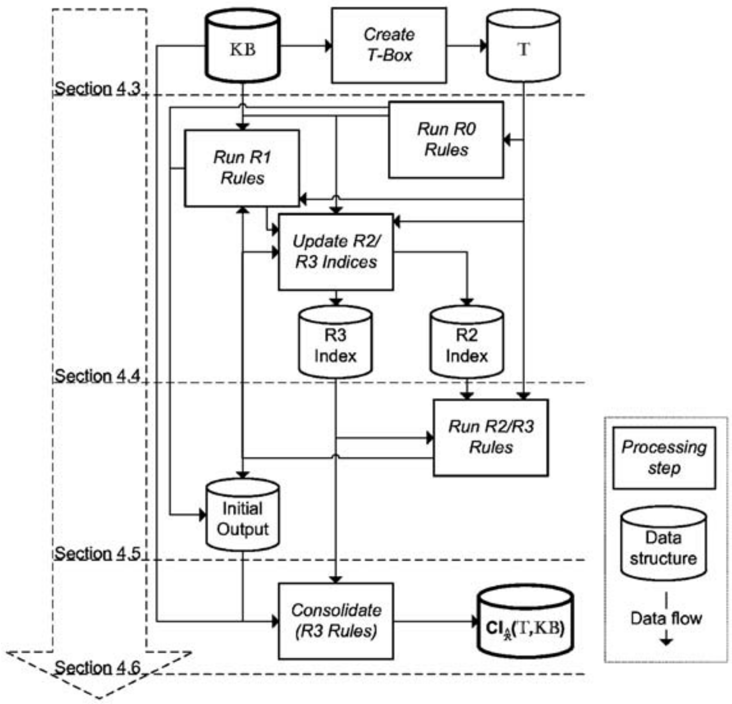
Algorithm Overview

The SAOR algorithm performs a fixpoint computation by iteratively applying the rules in Table 2. Figure 1 outlines the architecture. The reasoning process can be roughly divided into the following steps:

1. Separate $\mathbb{T}$ from $\mathbb{KB}$, build in-memory representation $\mathbb{T}$, and apply ruleset $\mathcal{R}0$ (Section 4.3).
2. Perform reasoning over $\mathbb{KB}$ in a statement-wise manner (Section 4.4):
   - 2.1 Execute rules with only a single A-Box triple pattern in the antecedent ($\mathcal{R}1$): join A-Box pattern with in-memory T-Box; recursively execute steps over inferred statements; write inferred RDF statements to output file.
   - 2.2 Write on-disk files for computation of rules with multiple A-Box triple patterns in the antecedent ($\mathcal{R}2$); when a statement matches one of the A-Box triple patterns for these rules and the necessary T-Box join exists, the statement is written to the on-disk file for later rule computation.
   - 2.3 Write on-disk equality file for rules which involve equality reasoning ($\mathcal{R}3$); `:sameAs` statements found during the scan are written to an on-disk file for later computation.
3. Execute ruleset $\mathcal{R}3 \cup \mathcal{R}3$: on-disk files containing partial A-Box instances for rules in $\mathcal{R}2$ and $\mathcal{R}3$ are sequentially analysed producing further inferred statements. Newly inferred statements are again subject to step 2 above; fresh statements can still be written to on-disk files and so the process is iterative until no new statements are found (Section 4.5).
4. Finally, consolidate source data along with inferred statements according to `:sameAs` computation ($\mathcal{R}3$) and write to final output (Section 4.6).

In the following sections, we discuss the individual components and processes in the architecture as highlighted, whereafter, in Section 4.7 we show how these elements are combined to achieve closure.

Figure 1. High-level architecture



Handling Terminological Data

In the following, we describe how to separate the T-Box data and how to create the data structures for representing the T-Box.

T-Box data from RDFS and OWL specifications can be acquired either from conventional crawling techniques, or by accessing the locations pointed to by the dereferenced URIs of classes and properties in the data. We assume for brevity that all the pertinent terminological data have already been collected and exist within the input data. If T-Box data are sourced separately via different means we can build an in-memory representation directly, without requiring the first scan of all input data.

We apply the following algorithm to create the T-Box in-memory representation, which we will analyse in the following sections:

- *FULL SCAN 1:* separate T-Box information as described in Definition 1.
- *TBOX SCAN 1 & 2:* reduce irrelevant RDF collection statements.
- *TBOX SCAN 3:* perform authoritative analysis of the T-Box data and load in-memory representation.

Separating and Reducing T-Box Data

Firstly, we wish to separate all possible T-Box statements from the main bulk of data. $\mathcal{P}_{SAOR}$ and $\mathcal{C}_{SAOR}$ are stored in memory and then the data dump is scanned. Quadruples with property $\in \mathcal{P}_{SAOR} \cup \{$ `rdf:first`, `rdf:rest` $\}$ or `rdf:type` statements with object $\in \mathcal{C}_{SOAR}$ (which, where applicable, abide by the OWL abstract syntax) are buffered to a T-Box data file.

However, the T-Box data file still contains a large amount of RDF collection statements (property ∈ { `rdf:first`, `rdf:rest` }) which are not related to reasoning. SAOR is only interested in such statements wherein they form part of a `:unionOf`, `:intersectionOf` or `:oneOf` class description. Later when the T-Box is being loaded, these collection fragments are reconstructed in-memory and irrelevant collection fragments are discarded; to reduce the amount of memory required we can quickly discard irrelevant collection statements through two T-Box scans:

- scan the T-Box data and store contexts of statements where the property ∈ { `:unionOf`, `:intersectionOf`, `:oneOf` }.
- scan the T-Box data again and remove statements for which both hold:
  - property ∈ { `rdf:first`, `rdf:rest` }
  - the context does not appear in those stored from the previous scan.

These scans quickly remove irrelevant collection fragments where a `:unionOf`, `:intersectionOf`, `:oneOf` statement does not appear in the same source as the fragment (i.e., collections which cannot contribute to the T-Box pattern of one of our rules).

Authoritative Analysis

We next apply authoritative analysis to the T-Box and load the results into our in-memory representation; in other words, we build an *authoritative T-Box* which pre-computes authority of T-Box data. We denote our authoritative T-Box by $\widehat{\mathbb{T}}$, whereby $\mathcal{C}l_{\widehat{\mathcal{R}}}(\mathbb{T}, \mathbb{KB}) = \mathcal{C}l_{\mathcal{R}}(\widehat{\mathbb{T}}, \mathbb{KB})$; for each rule, $\widehat{\mathbb{T}}$ only contains T-Box pattern instances for $\mathcal{A}nte_{\mathcal{T}}$ which can lead to an authoritative rule application.

Each statement read is initially matched without authoritative analysis against the patterns

rdfc3c	?C :intersectionOf ($\mathbf{?C_1}$ ... $\mathbf{?C_n}$) .	{ $\mathbf{?C_1}$, ..., $\mathbf{?C_n}$ } $\xrightarrow{\text{rdfc3c}}$?C
rdfc4a	?C :cardinality 1 ; :onProperty ?P .	?C $\xleftrightarrow{\text{rdfc4a}}$?P
rdfc4b	?C :maxCardinality 1 ; :onProperty ?P .	?C $\xleftrightarrow{\text{rdfc4b}}$?P

enumerated in Table 3. If a pattern is initially matched, the positions required to be authoritative, as identified in boldface, are checked. If one such authoritative check is satified, the pattern is loaded into the T-Box. Indeed the same statement may be matched by more than one T-Box pattern for different rules with different authoritative restrictions; for example the statement `foaf:name :equivalentProperty my:name .` retrieved from `my:` namespace matches the T-Box pattern of rules **rdfp13a′** & **rdfp13b′**, but only conforms to the authoritative restriction for rule **rdfp13b′**. Therefore, we only store the statement in such a fashion as to apply to rule **rdfp13b′**; that is, the authoritative T-Box stores T-Box pattern instances separately for each rule, according to the authoritative restrictions for that rule.

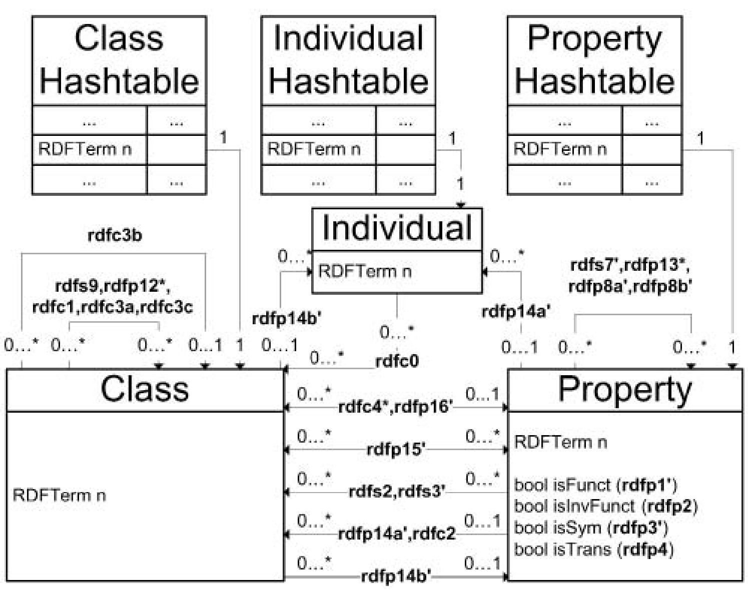
Checking the authority of a source for a given namespace URI, as presented in Definition 6, may require a HTTP connection to the namespace URI so as to determine whether a redirect exists to the authoritative document (HTTP Response Code 303). Results of accessing URIs are cached once in-memory so as to avoid establishing repetitive connections. If the pattern is authoritatively matched, the statement is reflected in the in-memory T-Box. Alternatively, where available, a crawler can provide a set of redirect pairs which can be loaded into the system to avoid duplicating HTTP lookups; we presume for generality that such information is not provided.

In-Memory T-Box

Before we proceed, we quickly discuss the storage of `:oneOf` constructs in the T-Box for rule **rdfc0**. Individuals ($?x_1 \ldots ?x_n$) are stored with pointers to the one-of class ?C. Before input data are read, these individuals are asserted to be of the `rdf:type` of their encompassing one-of class.

Besides the one-of support, for the in-memory T-Box we employ two separate hashtables, one for classes and another for properties, with RDF terms as key and a Java representation of the class or property as value. The representative Java objects contain labelled links to related objects as defined in Table 3 and Figure 2. The property and class objects are designed to contain all of the infor-

Figure 2. In-memory T-Box structure



mation required for reasoning on a membership assertion of that property or class: that is, classes/properties satisfying the A-Box antecedent pattern of a rule are linked to the classes/properties appearing in the consequent of that rule, with the link labelled according to that rule. During reasoning, the class/property identifier used in the membership assertion is sent to the corresponding hashtable and the returned internal object used for reasoning on that assertion. The objects contain the following:

- Property objects contain the property URI and references to objects representing domain classes (**rdfs2)**, range classes **(rdfs3′)**, super properties **(rdfs7')**, inverse properties **(rdfs8*)** and equivalent properties **(rdfp13*)**. References are kept to restrictions where the property in question is the object of an `:onProperty` statement (**rdfp14a′, rdfp16′, rdfc2, rdfc4*)**. Where applicable, if the property is part of a some-values-from restriction, a pointer is kept to the some-values-from class **(rdfp15′)**. Boolean values are stored to indicate whether the property is functional **(rdfp1′)**, inverse-functional **(rdfp2)**, symmetric **(rdfp3′)** and/or transitive **(rdfp4)**.
- Class objects contain the class URI and references to objects representing super classes **(rdfs9)**, equivalent classes **(rdfp12*)** and classes for which this class is a component of a union **(rdfc1)** or intersection **(rdfc3b/c)**. On top of these core elements, different references are maintained for different types of class description:
  - intersection classes store references to their constituent class objects **(rdfc3a)**
  - restriction classes store a reference to the property the restriction applies to **(rdfp14b′, rdfp15′, rdfc2, rdfc4*)** and also, if applicable to the type of restriction:
    - the values which the restriction property must have **(rdfp14b′)**
    - the class for which this class is a some-values-from restriction value **(rdfp15′)**

The algorithm must also performs in-memory joining of collection segments according to `rdf:first` and `rdf:rest` statements found during the scan for the purposes of building union, intersection and enumeration class descriptions. Again, any remaining collections not relevant to the T-Box segment of the knowledge-base (i.e., not terminological collection statements) are discarded at the end of loading the input data; we also discard cyclic and branching lists as well as any lists not found to end with the `rdf:nil` construct.

We have now loaded the final T-Box for reasoning into memory; this T-Box will remain fixed throughout the whole reasoning process.

Initial Input Scan

Having loaded the terminological data, SAOR is now prepared for reasoning by statement-wise scan of the assertional data. We provide the high-level flow for reasoning over an input statement in Function 1. The reasoning scan process can be described as recursive depth-first reasoning whereby each unique statement produced is again input immediately for reasoning. Statements produced thus far for the original input statement are kept in a set to provide uniqueness testing and avoid cycles; a uniquing function is maintained for a common subject group in the data, ensuring that statements are only produced once for that statement group. Once all of the statements produced by a rule have been themselves recursively analysed, the reasoner moves on to analysing the proceeding rule and loops until no unique statements are inferred.

```
Function 1:ReasonStatement(s)
  Input: statement s
  Global: T, index, output
  foreach rule r ∈ R1 do
      fire rule r w.r.t s and T;
      foreach inferred statement: i do
          if i is unique then
              if i is valid RDF then
                  write to output;
              ReasonStatement (i) ;
  foreach rule r ∈ R2 ∪ R3 do
      if s relevant for r w.r.t. T then
          write s to index, ;
```

There are three disjoint categories of statements which require different handling: namely (i) `rdf:type` statements, (ii) `:sameAs` statements, (iii) all other statements. We assume disjointness between the statement categories: we do not allow any external extension of the core `rdf:type`/ `:sameAs` semantics (non-standard use / non-authoritative extension). Further, the assertions about `rdf:type` in the RDFS specification define the `rdfs:domain` and `rdfs:range` of `rdf:type` as being `rdfs:Resource` and `rdfs:Class`; since we are not interested in inferring membership of such RDFS classes we do not subject `rdf:type` statements to property-based entailments. The only assertions about `:sameAs` from the OWL specification define domain and range as `:Thing` which we ignore by the same justification.

The `rdf:type` statements are subject to class-based entailment reasoning and require joins with class descriptions in the T-Box. The `:sameAs` statements are handled by ruleset $\mathcal{R}3$, which we discuss in Section 4.6. All other statements are subject to property-based entailments and thus requires joins with T-Box property descriptions.

Ruleset $\mathcal{R}2 \bigcup \mathcal{R}3$ cannot be computed solely on a statement-wise basis. Instead, for each rule, we assign an on-disk file (blocked and compressed to save disk space). Each file contains statements which may contribute to satisfying the antecedent of its pertinent rule. During the scan, if an A-Box statement satisfies the necessary T-Box join for a rule, it is written to the index for that rule. For example, when the statement

> `ex:me foaf:isPrimaryTopicOf ex:myHomepage .`

is processed, the property object for `foaf:isPrimaryTopicOf` is retrieved from the T-Box property hashtable. The object states that this property is of type `:InverseFunctionalProperty`. The rule cannot yet be fired as this statement alone does not satisfy the A-Box segment of the antecedent of **rdfp2** and the method is privy to only one A-Box statement at a time. When, later, the statement:

> `ex:me2 foaf:isPrimaryTopicOf ex:myHomepage .`

is found, it also is written to the same file – the file now contains sufficient data to (although it cannot yet) fire the rule and infer:

> `ex:me :sameAs ex:me2 .`

During the initial scan and inferencing, all files for ruleset $\mathcal{R}2 \bigcup \mathcal{R}3$ are filled with pertinent statements analogously to the example above. After the initial input statements have been exhausted, these files are analysed to infer, for example, the `:sameAs` statement above.

On-Disk A-Box Join Analysis

In this section, we discuss handling of the on-disk files containing A-Box statements for ruleset $\mathcal{R}2 \bigcup \mathcal{R}3$. We firstly give a general overview of the execution for each rule using an on-disk file and then look at the execution of each rule.

Table 4 presents the joins to be executed via the on-disk files for each rule: the key join variables, used for computing the join, are shown in boldface. In this table we refer to *SPOC and OPSC sorting order:* these can be intuitively interpreted as quads sorted according to subject, predicate,

Table 4. Table enumerating the A-Box joins to be computed using the on-disk files with key join variables in boldface font and sorting order required for statements to compute join

object, context (natural sorting order) and object, predicate, subject, context (inverse sorting order) respectively. For the internal index files, we use context to encode the sorting order of a statement and the iteration in which it was added; only joins with at least one new statement from the last iteration will infer novel output.

Again, an on-disk file is dedicated for each rule/join required. The joins to be computed are a simple "star shaped" join pattern or "one-hop" join pattern (which we reduce to a simple star shaped join computation by inverting one one or more patterns to inverse order). The statements in each file are initially sorted according to the key join variable. Thus, common bindings for the key join variable are grouped together and joins can be executed by means of sequential scan for common key join variable binding groups.

We now continue with a more detailed description of the process for each rule beginning with the more straightforward rules.

Functional Property Reasoning - Rule *rdfp1′*

From the initial input scan, we have a file containing only statements with functional properties in the predicate position (as described in Section 4.4). As can be seen from Table 4, the key join variable is in the subject position for all A-Box statements in the pattern. Thus, we can sort the file according to SPOC (natural) order. The result is a file where all statements are grouped according to a common subject, then predicate, then object. We can now scan this file, storing objects with a common subject-predicate. We can then fire the rule stating equivalence between these objects.

Inverse Functional Reasoning - ***Rule rdfp2***

Reasoning on statements containing inverse functional properties is conducted analogously to functional property reasoning. However, the key join variable is now in the object position for all A-Box statements in the pattern. Thus, we instead sort the file according to OPSC (inverse) order and scan the file inferring equivalence between the subjects for a common object-predicate group.

Intersection Class Reasoning - Rule *rdfc3c*

The key join variable for rule rdfc3c is in the subject position for all A-Box triple patterns. Thus we can sort the file for the rule (filled with memberships assertions for classes which are part of some intersection) according to SPOC order. We can scan common subject-predicate (in any case, the predicates all have value `rdf:type`) groups storing the objects (all types for the subject resource which are part of an intersection). The containing intersection for each type can then be retrieved and the intersection checked to see if all of it's constituent types have been satisfied. If so, membership of the intersection is inferred.

All-Values-From Reasoning - Rule *rdfp16′*

Again, the key join variable for rule **rdfp16'** is in the subject position for all A-Box triple patterns and again we can sort the file according to SPOC order. For a common subject group, we store `rdf:type` values and also all predicate/object edges for the given subject. For every membership assertion of an all-values-from restriction class (as is given by all of the `rdf:type` statements in the file), we wish to infer that objects of the `:onProperty` value (as is given by all the non-`rdf:type` statements) are of the all-values-from class. Therefore, for each restriction membership assertion, the objects of the corresponding `:onProperty`-value membership-assertions are inferred to be members of the all-values-from object class (`?D`).

Some-Values-From Reasoning - Rule *rdfp15′*

For some-values-from reasoning, the key join variable is in the subject position for `rdf:type` statements (all membership assertions of a some-values-from object class) but in the object position for the `:onProperty` membership assertions. Thus, we order class membership assertions in the file according to natural SPOC order and property membership assertions according to inverse OPSC order. In doing so, we can scan common `?y` binding groups in the file, storing `rdf:type` values and also all predicate/subject edges. For every member of a some-values-from object class (as is given by all of the `rdf:type` statements in the file according to the join with the T-Box on the `?D` position), we infer that subjects of the `:onProperty`-value statements (as is given by all the non-`rdf:type` statements according to the T-Box join with `?P`) are members of the restriction class (`?C`).

Transitive Reasoning (Non-Symmetric) - *Rule rdfp4*

Transitive reasoning is perhaps the most challenging to compute: the output of rule **rdfp4** can again recursively act as input to the rule. For closure, recursive application of the rule must be conducted in order to traverse arbitrarily long transitive paths in the data.

Firstly, we will examine sorting order. The key join variable is in the subject position for one pattern and in the object position for the second pattern. However, both patterns are identical: a statement which matches one pattern will obviously match the second. Thus, every statement in the transitive reasoning file is duplicated with one version sorted in natural SPOC order, and another in inverse OPSC.

Take for example the following triples where `ex:comesBefore` is asserted as being of type `:TransitiveProperty` in the T-Box:

```
>    INPUT:
>    ex:a ex:comesBefore ex:b .
>    ex:b ex:comesBefore ex:c .
>    ex:c ex:comesBefore ex:d .
```

In order to compute the join, we must write the statements in both orders, using the context to mark which triples are in inverse order, and sort them accordingly (for this internal index, we temporarily relax the requirement that context is a URI).

```
>    SORTED FILE - ITERATION 1:[13]
>    ex:a ex:comesBefore ex:b _:spoc1 .
>    ex:b ex:comesBefore ex:a _:opsc1 .
```

```
>    ex:b ex:comesBefore ex:c _:spoc1 .
>    ex:c ex:comesBefore ex:b _:opsc1 .
>    ex:c ex:comesBefore ex:d _:spoc1 .
>    ex:d ex:comesBefore ex:c _:opsc1 .
```

The data, as above, can then be scanned and for each common join-binding/predicate group (e.g., `ex:b ex:comesBefore`), the subjects of statements in inverse order (e.g., `ex:a`) can be linked to the object of naturally ordered statements (e.g., `ex:c`) by the transitive property. However, such a scan will only compute a single one-hop join. From above, we only produce:

```
>    OUTPUT - ITERATION 1 / INPUT - ITERATION
     2:
>    ex:a ex:comesBefore ex:c .
>    ex:b ex:comesBefore ex:d .
```

We still not have not computed the valid statement `ex:a ex:comesBefore ex:d .` which requires a two hop join. Thus we must iteratively feedback the results from one scan as input for the next scan. The output from the first iteration, as above, is also reordered and sorted as before and merge-sorted into the main

```
>    SORTED FILE - ITERATION 2:
>    ex:a ex:comesBefore ex:b _:spoc1 .
>    ex:a ex:comesBefore ex:c _:spoc2 .
>    ex:b ex:comesBefore ex:a _:opsc1 .
>    ex:b ex:comesBefore ex:c _:spoc1 .
>    ex:b ex:comesBefore ex:d _:spoc2 .
>    ex:c ex:comesBefore ex:a _:opsc2 .
>    ex:c ex:comesBefore ex:b _:opsc1 .
>    ex:c ex:comesBefore ex:d _:spoc1 .
>    ex:d ex:comesBefore ex:b _:opsc2 .
>    ex:d ex:comesBefore ex:c _:opsc1 .
```

The observant reader may already have noticed from above that we also mark the context with the iteration for which the statement was added. In every iteration, we only compute inferences which involve the delta from the last iteration; thus the process is comparable to semi-naïve evaluation. Only joins containing at least one newly added statement are used to infer new statements for output. Thus, from above, we avoid repeat inferences from ***ITERATION*** 1 and instead infer:

```
>    OUTPUT - ITERATION 2:
>    ex:a ex:comesBefore ex:d .
```

A fixpoint is reached when no new statements are inferred. Thus we would require another iteration for the above example to ensure that no new statements are inferable. The number of iterations required is in $\bigcirc(\log n)$ according to the longest unclosed transitive path in the input data. Since the algorithm requires scanning of not only the delta but all data, performance using on-disk file scans alone would be sub-optimal. For example, if one considers that most of the statements constitute paths of, say ≤8 vertices, one path containing 128 vertices would require four more scans after the bulk of the paths have been closed.

With this in mind, we accelerate transitive closure by means of an in-memory transitivity index. For each transitive property found, we store sets of linked lists which represent the graph extracted for that property. From the example ***INPUT*** from above, we would store.

```
>    ex:comesBefore | ex:a -> ex:b -> ex:c ->
     ex:d
```

From this in-memory linked list, we would then collapse all paths of length ≥2 (all paths of length 1 are input statements) and infer closure at once:

```
>    OUTPUT - ITERATION 1 / INPUT - ITERATION
     2:
>    ex:a ex:comesBefore ex:c .
>    ex:a ex:comesBefore ex:d .
>    ex:b ex:comesBefore ex:d .
```

Obviously, for scalability requirements, we do not expect the entire transitive body of statements to fit in-memory. Thus, before each iteration we calculate the in-memory capacity and only store a pre-determined number of properties and vertices. Once the in-memory transitive index is full, we infer the appropriate statements and continue by file-scan. The in-memory index is only used to store the delta for a given iteration (everything for the first iteration). Thus, we avoid excess iterations to compute closure of a small percentage of statements which form a long chain and greatly accelerate the fixpoint calculation.

Transitive Reasoning (Symmetric) - Rules *rdfp3′/rdfp4*

We use a separate on-disk file for membership assertions of properties which are both transitive and symmetric. A graph of symmetric properties is direction-less, thus the notion of direction as evident above though use of inverted ordered statements is unnecessary. Instead, all statements and their inverses (computed from symmetric rule **rdfp3′**) are written in natural SPOC order and direct paths are inferred between all objects in a common subject/predicate group. The in-memory index is again similar to above; however, we instead use a direction-less doubly-linked list.

Equality Reasoning - Ruleset $\mathcal{R}3$

Thus far, we have not considered `:sameAs` entailment, which is supported in SAOR through rules in $\mathcal{R}3$. Prior to executing rules **rdfp11′** & **rdfp11″**, we must first perform symmetric transitive closure on the list of all `:sameAs` statements (rules **rdfp6′** & **rdfp7**). Thus, we use an on-disk file analogous to that described in Section 4.5.7.

However, for rules **rdfp6′** & **rdfp7**, we do not wish to experience an explosion of inferencing through long equivalence chains (lists of equivalent individuals where there exists a `:sameAs` path from each individual to every other individual). The closure of a symmetric transitive chain of n vertices results in $n\ (n-1)$ edges or statements (ignoring reflexive statements). For example, in (Hogan, Harth et al. 2007) we found a chain of 85,803 equivalent individuals inferable from a Web dataset.[14] Naïvely applying symmetric transitive reasoning as discussed in Section 4.5.7 would result in a closure of 7.362b `:sameAs` statements for this chain alone.

Similarly, `:sameAs` entailment, as according to rules **rdfp11′** & **rdfp11″**, duplicates data for all equivalent individuals which could result in a massive amount of duplicate data (particularly when considering uniqueness on a quad level: i.e., including duplicate triples from different sources). For example, if each of the 85,803 equivalent individuals had attached an average of 8 unique statements, then this could equate to 8*85,803*85,803 = 59b inferred statements.

Obviously, we must avoid the above scenarios, so we break from complete inference with respect to the rules in $\mathcal{R}3$. Instead, for each set of equivalent individuals, we chose a pivot identifier to use in rewriting the data. The pivot identifier is used to keep a consistent identifier for the set of equivalent individuals: the alphabetically highest pivot is chosen for convenience of computation. For alternative choices of pivot identifiers on web data see (Hogan, Harth et al. 2007). We use the pivot identifier to consolidate data by rewriting all occurrences of equivalent identifiers to the pivot identifier effectively merging the equivalent set into one individual.

Thus, we do not derive the entire closure of `:sameAs` statements as indicated in rules **rdfp6′** & **rdfp7** but instead only derive an equivalence list which points from equivalent identifiers to their pivots. As highlighted, use of a pivot identifier is necessary to reduce the amount of output statements, effectively compressing equivalent resource descriptions: we hint here that a fully expanded view of the descriptions could instead be supported through backward-chaining over the semi-materialised data.

To achieve the pivot compressed inferences we use an on-disk file containing :sameAs statements. Take for example the following statements:

```
>    INPUT:
>    ex:a :sameAs ex:b .
>    ex:b :sameAs ex:c .
>    ex:c :sameAs ex:d .
```

We only wish to infer the following output for the pivot identifier ex:a:

```
>    OUTPUT PIVOT EQUIVALENCES:
>    ex:b :sameAs ex:a .
>    ex:c :sameAs ex:a .
>    ex:d :sameAs ex:a .
```

The process is the same as that for symmetric transitive reasoning as described before: however, we only close transitive paths to nodes with the highest alphabetical order. So, for example, if we have already materialised a path from ex:d to ex:a we ignore inferring a path from ex:d to ex:b as ex:b>ex:a.

To execute rules **rdfp11′** & **rdfp11″** and perform "consolidation" (rewriting of equivalent identifiers to their pivotal form), we perform a zig-zag join: we sequentially scan the :sameAs inference output as above and an appropriately sorted file of data, rewriting the latter data according to the :sameAs statements. For example, take the following statements to be consolidated:

```
>    UNCONSOLIDATED DATA:
>    ex:a foaf:mbox <mail@example.org> .
>    ...
>    ex:b foaf:mbox <mail@example.org> .
>    ex:b foaf:name "Joe Bloggs" .
>    ...
>    ex:d :sameAs ex:b .
>    ...
>    ex:e foaf:knows ex:d .
```

The above statements are scanned sequentially with the closed :sameAs pivot output from above. For example, when the statement ex:b foaf:mbox <mailto:mail@example.org> . is first read from the unconsolidated data, the :sameAs index is scanned until ex:b :sameAs ex:a . is found (if ex:b is not found in the :sameAs file, the scan is paused when an element above the sorting order of ex:b is found). Then, ex:b is rewritten to ex:a.

```
>    PARTIALLY CONSOLIDATED DATA:
>    ex:a foaf:mbox <mail@example.org> .
>    ...
>    ex:a foaf:mbox <mail@example.org> .
>    ex:a foaf:name "Joe Bloggs" .
>    ...
>    ex:a :sameAs ex:b .
>    ...
>    ex:e foaf:knows ex:d .
```

We have now executed rule **rdfp11′** and have the data partially consolidated as shown. However, the observant reader will notice that we have not consolidated the object of the last two statements. We must sort the data again according to inverse OPSC order and again sequentially scan both the partially consolidated data and the :sameAs pivot equivalences, this time rewriting ex:b and ex:d in the object position to ex:a and producing the final consolidated data. This equates to executing rule **rdfp11″.**

For the purposes of the on-disk files for computing rules requiring A-Box joins, we must consolidate the key join variable bindings according to the :sameAs statements found during reasoning. For example consider the following statements in the functional reasoning file:

```
>    ex:a ex:mother ex:m1 .
>    ex:b ex:mother ex:m2 .
```

Evidently, rewriting the key join position according to our example pivot file will lead to inference of:

```
>    ex:m1 :sameAs ex:m2
```

which we would otherwise miss. Thus, whenever the index of `:sameAs` statements is changed, for the purposes of closure it is necessary to attempt to rewrite all join index files according to the new `:sameAs` statements. Since we are, for the moment, only concerned with consolidating on the join position we need only apply one consolidation scan.

The final step in the SAOR reasoning process is to finalise consolidation of the initial input data and the newly inferred output statements produced by all rules from scanning and on-disk file analysis. Although we have provided exhaustive application of all inferencing rules, and we have the complete set of `:sameAs` statements, elements in the input and output files may not be in their equivalent pivotal form. Therefore, in order to ensure proper consolidation of all of the data according to the final set of `:sameAs` statements, we must firstly sort both input and inferred sets of data in SPOC order, consolidate subjects according to the pivot file as above; sort according to OPSC order and consolidate objects.

However, one may notice that `:sameAs` statements in the data become consolidated into reflexive statements: i.e., from the above example `ex:a :sameAs ex:a` . Thus, for the final output, we remove any `:sameAs` statements in the data and instead merge the statements contained in our final pivot `:sameAs` equivalence index, and their inverses, with the consolidated data. These statements retain the list of all possible identifiers for a consolidated entity in the final output.

Achieving Closure

We conclude this section by summarising the approach, detailing the overall fixpoint calculations (as such, putting the jigsaw together) and detailing how closure is achieved using the individual components. Along these lines, in Algorithm 2, we provide a summary of the steps seen so far and, in particular, show the fixpoint calculations involved for exhaustive application of ruleset $\mathcal{R}2 \cup \mathcal{R}3$; we compute one main fixpoint over all of the operations required, within which we also compute two local fixpoints.

Firstly, since all rules in $\mathcal{R}2$ are dependant on `:sameAs` equality, we perform `:sameAs` inferences first. Thus, we begin closure on $\mathcal{R}2 \cup \mathcal{R}3$ with a local equality fixpoint which (i) executes all rules which produce `:sameAs` inferences (**rdfp1′,rdfp2,rdfc4***); (ii) performs symmetric-transitive closure using pivots on all `:sameAs` inferences; (iii) rewrites **rdfp1′, rdfp2** and **rdfc4*** indexes according to `:sameAs` pivot equivalences and (iv) repeats until no new `:sameAs` statements are produced.

Next, we have a local transitive fixpoint for recursively computing transitive property reasoning: (i) the transitive index is rewritten according to the equivalences found through the above local fixpoint; (ii) a transitive closure iteration is run, output inferences are recursively fed back as input; (iii) ruleset $\mathcal{R}1$ is also recursively applied over output from previous step whereby the output from ruleset $\mathcal{R}1$ may also write new statements to any $\mathcal{R}2$ index. The local fixpoint is reached when no new transitive inferences are computed.

Finally, we conclude the main fixpoint by running the remaining rules: **rdfp15′, rdfp16′ and rdfc3c.** For each rule, we rewrite the corresponding index according to the equivalences found from the first local fixpoint, run the inferencing over the index and send output for reasoning through ruleset $\mathcal{R}1$. Statements inferred directly from the rule index, or through subsequent application of ruleset $\mathcal{R}1$, may write new statements for $\mathcal{R}2$ indexes. This concludes one iteration of the main fixpoint, which is run until no new statements are inferred.

For each ruleset $\mathcal{R}0$ - $\mathcal{R}3$, we now justify our algorithm in terms of our definition of closure with respect to our static T-Box. Firstly, closure is achieved immediately upon ruleset $\mathcal{R}0$, which requires only T-Box knowledge, from our static

Algorithm 2.

```
Algorithm 2: SAOR reasoning algorithm
Input: KB
Output: Cl_R̂(T,KB)
for scan KB (Section 4.3.1) do
    obtain candidate statements for T;

// output contains R0 ∪ R1 inferences for initial input
// index contains initial statements relevant for R2
// sameas contains initial statements relevant for R3
repeat
    repeat
        for rule r ∈ {rdfp1',rdfp2,rdfc4*} (Sect. 4.5) do
            if new_r is set then
                rewrite index_r w.r.t. sameas/ unset new_r;
            if index_r has changed or was rewritten then
                run r on index_r;
                write to sameas;
        if sameas has changed then
            run rules rdfp6' and rdfp7 on sameas (Sect. 4.6) ;
            write sameas/ set all new;
    until fixpoint reached (no changes in previous iteration) ;
    if new_rdfp4 is set then
        rewrite index_rdfp4 w.r.t. sameas/ unset new_rdfp4;
    repeat
        run rule rdfp4 on index_rdfp4 (Sect. 4.5.6 and 4.5.7) ;
        for inferred statement i do
            write to index_rdfp4 ;
            if i is RDF then
                write to output;
            ReasonStatement (i) (Funct. 1) ;
    until fixpoint reached (no changes in previous iteration) ;
    for rule r ∈ {rdfp15',rdfp16',rdfc3c} (Sect. 4.5) do
        if new_r is set then
            rewrite index_r w.r.t. sameas/ unset new_r;
        if index_r has changed or was rewritten then
            run r on index_r;
            for inferred statement i do
                if i is RDF then
                    write to output;
                ReasonStatement (i) (Funct. 1) ;
until fixpoint reached (no changes in previous iteration) ;
// output contains all inferences in non-pivotal form
for subject and object (Sect. 4.6) do
    for scan KB and output do
        rewrite according to sameas;
        write to Cl_R̂(T,KB);
    write sameas and sameas⁻ to Cl_R̂(T,KB);
```

T-Box. Secondly, with respect to the given T-Box, every input statement is subject to reasoning according to ruleset $\mathcal{R}1$, as is every statement inferred from ruleset $\mathcal{R}0$, those recursively inferred from ruleset $\mathcal{R}1$ itself, and those recursively inferred from on-disk analysis for ruleset $\mathcal{R}1 \bigcup \mathcal{R}2$. Next, every input statement is subject to reasoning according to ruleset $\mathcal{R}2$ with respect to our T-Box; these again include all inferences from $\mathcal{R}0$, all statements inferred through $\mathcal{R}1$ alone, and all inferences from recursive application of ruleset $\mathcal{R}1 \bigcup \mathcal{R}2$.

Therefore, we can see that our algorithm applies exhaustive application of ruleset $\mathcal{R}0 \bigcup \mathcal{R}1 \bigcup \mathcal{R}2$ with respect to our T-Box, leaving only consideration of equality reasoning in ruleset $\mathcal{R}3$. Indeed, our algorithm is not complete with respect to ruleset $\mathcal{R}3$ since we choose pivot identifiers for representing equivalent individuals as justified in Section 4.6. However, we still provide a form of "pivotal closure" whereby backward-chaining support of rules **rdfp11′** and **rdfp11″** over the output of our algorithm would provide a view of closure as defined; i.e., our output contains all of the possible inferences according to our notion of closure, but with equivalent individuals compressed in pivotal form.

Firstly, for rules **rdfp6′** and **rdfp7**, all statements where p = `:sameAs` from the original input or as produced by $\mathcal{R}0 \bigcup \mathcal{R}1 \bigcup \mathcal{R}2$ undergo on-disk symmetric-transitive closure in pivotal form. Since both rules only produce more `:sameAs` statements, and according to the standard usage restriction of our closure, they are not applicable to reasoning under $\mathcal{R}0 \bigcup \mathcal{R}1 \bigcup \mathcal{R}2$. Secondly, we loosely apply rules **rdfp11′ and rdfp11″** such as to provide closure with respect to joins in ruleset $\mathcal{R}2$; i.e., all possible joins are computed with respect to the given `:sameAs` statements. Equivalence is clearly not important to $\mathcal{R}0$ since we strictly do not allow `:sameAs` statements to affect our T-Box; $\mathcal{R}1$ inferences do not require joins and, although the statements produced will not be in pivotal form, they will be output and rewritten later; inferences from $\mathcal{R}2$ will be produced as discussed, also possibly in non-pivotal form. In the final consolidation step, we then rewrite all statements to their pivotal form and provide incoming and outgoing `:sameAs` relations between pivot identifiers and their non-pivot equivalent

Table 5. Comparison of authoritative and non-authoritative reasoning for the number of unique inferred RDF statements produced (w.r.t. ruleset $\mathcal{R}1$ over) the five most frequently occurring classes and properties in both input datasets. '' indicates a datatype property where the object of $m(P)$ is a literal. The amount of statements produced for authoritative reasoning for a single membership assertion of the class or property is denoted by $|\mathcal{C}l_{\mathcal{R}1}(\widehat{\mathbb{T}}, \{m(C)\})|$ and $|\mathcal{C}l_{\mathcal{R}1}(\widehat{\mathbb{T}}, \{m(P)\})|$ respectively. Non-authoritative counts are given by $|\mathcal{C}l_{\mathcal{R}1}(\mathbb{T}, \{m(C)\})|$ and $|\mathcal{C}l_{\mathcal{R}1}(\mathbb{T}, \{m(P)\})|$. n is the number of membership assertions for the class C or property P in the given dataset.*

identifiers. This constitutes our output, which we call *pivotal authoritative closure*.

EVALUATION AND DISCUSSION

We now provide evaluation of the SAOR methodology firstly with quantitative analysis of the importance of authoritative reasoning, and secondly we provide performance measurements and discussion along with insights into the fecundity of each rule w.r.t. reasoning over web data. All experiments are run on one machine with a single Opteron 2.2 GHz CPU and 4 GB of main memory. We provide evaluation on two datasets: we provide complete evaluation for a dataset of 147m statements collected from 665k sources and scale-up experiments running scan-reasoning (rules in $\mathcal{R}0 \cup \mathcal{R}1$) on a dataset of 1.1b statements collected from 6.5m sources; both datasets are from web-crawls using MultiCrawler (Harth, Umbrich et al. 2006). We create a unique set of blank nodes for each graph $\mathcal{G}' \in M(\mathcal{S}_{\mathcal{W}})$ using a function on c and the original blank node label which ensures a one-to-one mapping from the original blank node labels and uniqueness of the blank nodes for a given context c.

To show the effects of ontology hijacking we constructed two T-Boxes with and without authoritative analysis for each dataset. We then ran reasoning on single membership assertions for the top five classes and properties found natively in each dataset. Table 5 summarises the results. Taking `foaf:Person` as an example, with an authoritative T-Box, six statements are output for every input `rdf:type foaf:Person` statement in both datasets. With the non-authoritative T-Box, 388 and 4,631 statements are output for every such input statement for the smaller and larger datasets respectively. Considering that there are 3.25m and 63.33m such statements in the respective datasets, overall output for `rdf:type foaf:Person` input statements alone approach 1.26b and 293b statements for non-authoritative reasoning respectively. With authoritative reasoning we only produce 19.5m and 379.6m statements, a respective saving of 65x and 772x on output statement size.[15]

It should be noted that reasoning on a membership assertion of the top level class (`:Thing`/ `rdfs:Resource`) is very large for both the 147m (234 inferences) and the 1.1b dataset (4251 inferences). For example, in both datasets, there are many `:unionOf` class descriptions with `:Thing` as a member;[16] for the 1.1b dataset, many inferences on the top level class stem from, for example, the OWL W3C Test Repository[17]. Of course we do not see such documents as being malicious in any way, but clearly they would cause inflationary inferences when naïvely considered as part of web knowledge-base.

Next, we present some metrics regarding the first step of reasoning: the separation and in-memory construction of the T-Box. For the 1.1b dataset, the initial scan of all data found 9,683,009 T-Box statements (0.9%). Reducing the T-Box by removing collection statements as described in Section 4.3.1 dropped a further 1,091,698 (11% of total) collection statements leaving 733,734 such statements in the T-Box (67% collection statements dropped) and 8,591,311 (89%) total. Table 6 shows, for membership assertions of each class and property in $\mathcal{C}_{SAOR}$ and $\mathcal{P}_{SAOR}$, the result of applying authoritative analysis. Of the 33,157 unique namespaces probed, 769 (2.3%) had a redirect, 4068 (12.3%) connected but had no redirect and 28,320 (85.4%) did not connect at all. In total, 14,227,116 authority checks were performed. Of these, 6,690,704 (47%) were

negative and 7,536,412 (53%) were positive. Of the positive, 4,236,393 (56%) were blank-nodes, 2,327,945 (31%) were a direct match between namespace and source and 972,074 (13%) had a redirect from the namespace to the source. In total, 2,585,708 (30%) statements were dropped as they could not contribute to a valid authoritative inference. The entire process of separating, analysing and loading the T-Box into memory took 6.47 hours: the most costly operation here is the large amount of HTTP lookups required for authoritative analysis, with many connections unsuccessful after our five second timeout. The process required ~3.5G of Java heap-space and ~10M of stack space.

For the 147m dataset, 2,649,532 (1.7%) T-Box statements were separated from the data, which was reduced to 1,609,958 (61%) after reducing the amount of irrelevant collection statements; a further 536,564 (33%) statements were dropped as they could not contribute to a valid authoritative inference leaving 1,073,394 T-Box statements (41% of original). Loading the T-Box into memory for the 147m dataset took 1.04 hours.

We proceed by evaluating the application of all rules on the 147m dataset. Figure 3 shows performance for reaching an overall fixpoint for application of all rules. Clearly, the performance plateaus after 79 mins. At this point the input statements have been exhausted, with rules in $\mathcal{R}0$ and $\mathcal{R}1$ having been applied to the input data and statements written to the on-disk files for $\mathcal{R}2$ and $\mathcal{R}3$. SAOR now switches over to calculating a fixpoint over the on-disk computed $\mathcal{R}2$ and $\mathcal{R}3$ rules, the results of which become the new input for $\mathcal{R}0$ and $\mathcal{R}1$ and further recursive input to the $\mathcal{R}2$ and $\mathcal{R}3$ files.

Figure 4 shows performance specifically for achieving closure on the on-disk $\mathcal{R}2$ and $\mathcal{R}3$ rules. There are three pronounced steps in the output of statements. The first one shown at (a) is due to inferencing of `:sameAs` statements from rule **rdfp2 (** `:InverseFunctionalProperty` - 2.1m inferences). Also part of the first step are `:sameAs` inferences from rules **rdfp1′** (`:FunctionalProperty` - 31k inferences) and rules **rdfc4*** **(**`:cardinality`/`:maxCardinality` - 449 inferences).

Figure 3. Performance of applying entire ruleset on the 147m statements dataset (without final consolidation step)

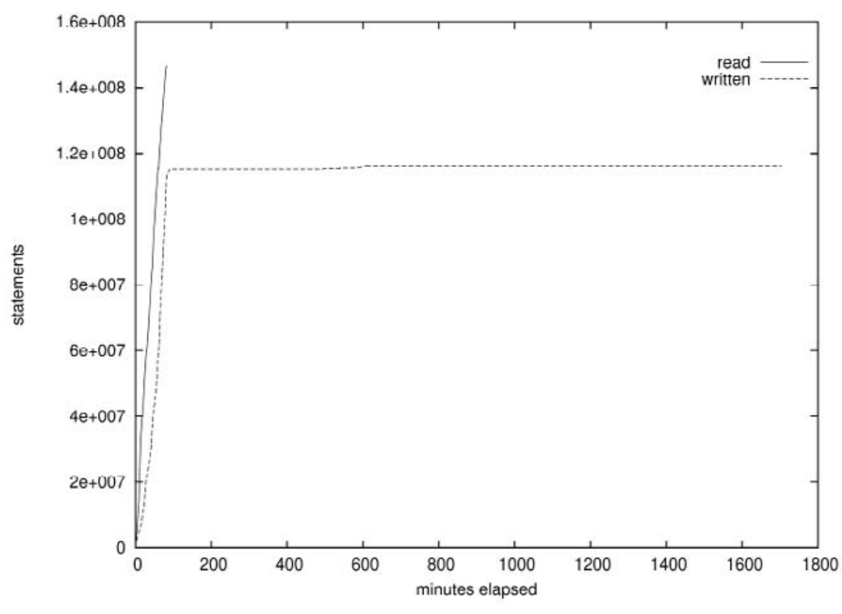

Figure 4. Performance of inferencing over $\mathcal{R}2$ and $\mathcal{R}3$ on-disk indexes for the 147m statements dataset (without final consolidation)

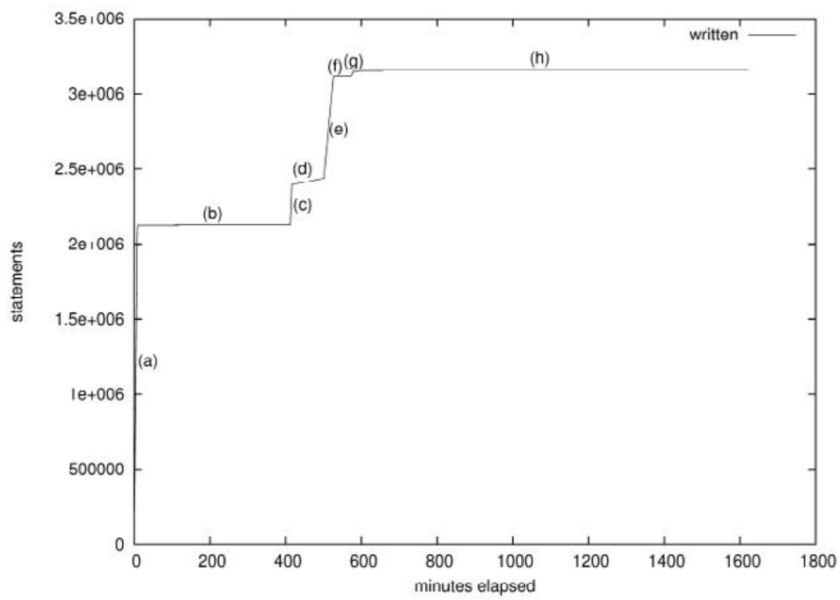


For the first plateau shown at (b), the `:sameAs` equality file is closed for the first time and a local fixpoint is being calculated to derive the initial `:sameAs` statements for future rules; also during the plateau at (b), the second iteration for the `:sameAs` fixpoint (which, for the first time, consolidates the key join variables in files for rules **rdfp2, rdfp1′, rdfc4a, rdfc4b according to all** `:sameAs` statements produced thus far) produces 1,018 new such statements, with subsequent iterations producing 145, 2, and 0 new statements respectively.

The second pronounced step at (c) is attributable to 265k transitive inferences, followed by 1.7k symmetric-transitive inferences. The proceeding slope at (d) is caused by inferences on **rdfc3c** (`:intersectionOf` - 265 inferences) and **rdfp15′** (`:someValuesFrom` - 36k inferences) with rule **rdfp16′** (`:allValuesFrom` - 678k inferences) producing the final significant step at (e). The first complete iteration of the overall fixpoint calculation is now complete.

Since the first local `:sameAs` fixpoint, 22k mostly `rdf:type` statements have been written back to the cardinality rule files, 4 statements to the `:InverseFunctionalProperty` file and 14 to the `:FunctionalProperty` file. Thus, the `:sameAs` fixpoint is re-executed at (f), with no new statements found. The final, minor, staggered step at (g) occurs after the second `:sameAs` fixpoint when, most notably, rule **rdfp4** (`:Transitive-Property`) produces 24k inferences, rule **rdfc3c** (`:intersectionOf`) produces 6.7k inferences, and rule **rdfp16′** (`:allValuesFrom`) produces 7.3k new statements.

The final, extended plateau at (h) is caused by rules which produce/consume `rdf:type` statements. In particular, the fixpoint encounters `:allValuesFrom` inferencing producing a minor contribution of statements (≤2) which lead to an update and re-execution of `:allValuesFrom` inferencing and `:intersectionOf` reasoning. In particular, `:allValuesFrom` required 66 recursive iterations to reach a fixpoint. We identified the problematic data as follows:

```
> @prefix veml: <http://www.icsi.berkeley.edu/snarayan/VEML.owl#>
> @prefix verl: <http://www.icsi.berkeley.edu/snarayan/VERL.owl#>
> @prefix data: <http://www.icsi.berkeley.edu/snarayan/meeting01.owl#>
> ...
> FROM veml: (T-BOX):
> veml:sceneEvents rdfs:range veml:EventList .
> veml:EventList rdfs:subClassOf _:r1 ; rdfs:subClassOf _:r2 .
> _:r1 :allValuesFrom verl:Event ; :onProperty rdf:first .
> _:r2 :allValuesFrom veml:EventList ; :onProperty rdf:rest .
> FROM data: (A-BOX):
> data:scene veml:sceneEvents ( data:1 , ..., data:65 ) .
> EXAMPLE COLLECTION SNIPPET:
> _:cN rdf:first data:N ; rdf:rest _:cN+1 .
```

From the above data, each iteration of :allValuesFrom reasoning and subsequent subclass reasoning produced:

```
> IN ALL-VALUES-FROM, ITER 0:
> FROM INPUT:
> ( _:c1 ... _:c65) rdf:first (data:1 ... data:65) .
> FROM RANGE:
> _:c1 a veml:EventList .
> OUTPUT ALL-VALUES-FROM, ITER N:
> _:dataN a verl:Event .
> _:cN+1 a veml:EventList .
> FROM SUBCLASS ON ABOVE
> ADDED TO ALL-VALUES-FROM, ITER N+1:
> _:cN+1 rdf:type _:r1 ; rdf:type _:r2.
```

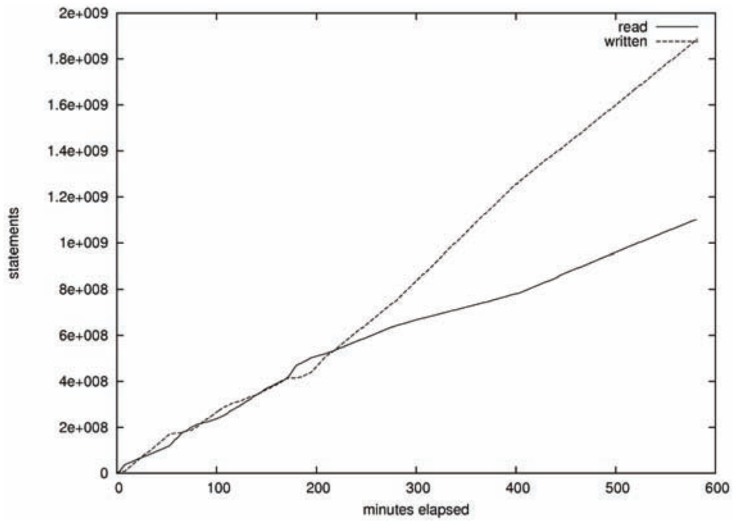
In particular, a small contribution of input statements requires a merge-sort and re-scan of the file in question. This could indeed be solved by implementing binary-search lookup functionality over the sorted files for small input from a previous round; however, this would break with our initial aim of performing reasoning using only the primitives of file-scanning and multi-way merge-sort.

Finally in the reasoning process, we must perform consolidation of the input data and the output inferred statements according to the `:sameAs` index produced in the previous step. The first step involves sorting the input and inferred data according to natural SPOC order; the process took 6.4 hours and rewrote 35.4m statements into pivotal form. The second step involves subsequent sorting of the data according to inverse OPSC order; the process took 8.2 hours and rewrote 8.5m statements. The expense of these steps is primarily attributable to applying multi-way merge-sorting over all data in both sorting orders.

Although the degradation of performance related to the on-disk fixpoint computation of ruleset $\mathcal{R}2 \cup \mathcal{R}3$ is significant, if one is prepared to trade completeness (as we define it) for computational efficiency, the fixpoint calculation can be restrained to only perform a small, known amount of iterations (e.g., inferencing of the majority of statements in Figure 4 takes place over approx. 3 hours). Only minute amounts of inferred statements are produced in latter iterations of the fixpoint.

Further still, most inferences are produced after the initial scan which takes approx. 79 minutes. Thus, even after application of only $\mathcal{R}0$ and $\mathcal{R}1$ rules, the majority of inferencing has been conducted. This simpler more practical reasoning subset exhibits linear scale, as is visible for the first stage of Figure 3 prior to the on-disk computations. Along these lines, we present in Figure 5 the performance of applying rules $\mathcal{R}0$ and $\mathcal{R}1$ to the 1.1b statement dataset, in one scan, with respect to the T-Box derived from that dataset as described above. In particular, we refer to the linear trend present; upon inspection, one can see that minor slow-down in the rate of statements read is attributable to an increased

Figure 5. Performance of applying ruleset $\mathcal{R}0 \cup \mathcal{R}1$ on the 1.1b dataset



throughput in terms of output statements (disk write operations).

Finally, Table 7 lists the number of times each rule was fired for reasoning on the 1.1b dataset, reasoning using only $\mathcal{R}0 \cup \mathcal{R}1$ on the 147m dataset and also of applying all rules to the 147m dataset. Again, from both Figure 3 and Table 7 we can deduce that the bulk of current web reasoning is covered by those rules ($\mathcal{R}0 \cup \mathcal{R}1$) which exhibit linear scale.

RELATED WORK

OWL reasoning, specifically query answering over OWL Full, is not tackled by typical DL Reasoners; such as FaCT++ (Haarslev and Möller 2003; Tsarkov and Horrocks 2006), RACER (Haarslev and Möller 2003) or Pellet (Sirin, Parsia et al. 2007); which focus on complex reasoning tasks such as subsumption checking and provable completeness of reasoning. Likewise, KAON2 (Motik 2006), which reports better results on query answering, is limited to OWL-DL expressivity due to completeness requirements. Despite being able to deal with complex ontologies in a complete manner, these systems are not tailored for the particular challenges of processing large amounts of RDF data and particularly large A-Boxes.

Systems such as TRIPLE (Sintek and Decker 2002), JESS[18], or Jena[19] support rule representable RDFS or OWL fragments as we do, but only work in-memory whereas our framework is focused on conducting scalable reasoning using persistent storage.

The OWLIM (Kiryakov, Ognyanov et al. 2005) family of systems allows reasoning over a version of pD* using the TRREE: Triple Reasoning and Rule Entailment Engine. Besides the in-memory version SwiftOWLIM, which uses TRREE, there is also a version offering query-processing over a persistent image of the repository, BigOWLIM, which comes closest technically to our approach. In evaluation on 2 x Dual-Core 2GHz machines with 16GB of RAM, BigOWLIM is claimed to index over 1 bn triples from the LUBM benchmark (Guo, Pan et al. 2005) in just under 70 hours ("BigOWLIM Sys. Doc.", 2006); however, this figure includes indexing of the data for query-answering, and is not directly comparable with our results, and in any case, our reasoning approach strictly focuses on sensible reasoning for web data.

Table 7. Count of number of statements inferred for applying the given ruleset on the given dataset.

Some existing systems already implement a separation of T-Box and A-Box for scalable reasoning, where in particular, assertional statements are stored in some RDBMS; e.g. DLDB (Pan and Heflin 2003), Minerva (Zhou, Ma et al. 2006) and OntoDB (Hondjack, Pierra et al. 2007). Similar to our approach of reasoning over web data, (Pan, Qasem et al. 2007) demonstrates reasoning over 166m triples using the DLDB system. Also like us, (and as we had previously introduced in (Hogan, Harth et al. 2007)) they internally choose pivot identifiers to represent equivalent sets of individuals. However, they use the notion of perspectives to support inferencing based on T-Box data; in their experiment they manually selected nine T-Box perspectives, unlike our approach that deals with arbitrary T-Box data from the Web. Their evaluation was performed on a workstation with dual 64-bit CPUs and 10GB main memory on which they loaded 760k documents / 166m triples (14% larger than our 147m statement dataset) in about 350 hrs; however, unlike our evaluation, the total time taken includes indexing for query-answering.

In a similar approach to our authoritative analysis, (Cheng, Ge et al. 2008) introduced restrictions for accepting sub-class and equivalent-class statements from third-party sources; they follow similar arguments to that made in this paper. However, their notion of what we call authoritativeness is based on hostnames and does not consider redirects; we argue that in both cases, e.g., use of PURL services[20] is not properly supported: (i) all documents using the same service (and having the same namespace hostname) would be 'authoritative' for each other, (ii) the document cannot be served directly by the namespace location, but only through a redirect. Indeed, further work presented in (Cheng and Qu 2008) introduced the notion of an *authoritative description* which is very similar to ours. In any case, we provide much more extensive treatment of the issue, supporting a much more varied range of RDF(S)/OWL constructs.

One promising alternative to authoritative reasoning for the Web is the notion of "context-dependant" or "quarantined reasoning" introduced in (Delbru, Polleres et al. 2008), whereby inference results are only considered valid within the given context of a document. As opposed to our approach whereby we construct one authoritative model for all web data, their approach uses a unique model for each document, based on implicit and explicit imports of the document; thus, they would infer statements within the local context which we would consider to be non-authoritative. However, they would miss inferences which can only be conducted by considering a merge of documents, such as transitive closure or equality inferences based on inverse-functional properties over multiple documents. Their evaluation was completed on three machines with quad-core 2.33GHz and 8GB main memory; they claimed to be able to load, on average, 40 documents per second.

CONCLUSION AND FUTURE WORK

We have presented SAOR: a system for performing reasoning over web data based on primitives known to scale: file-scan and sorting. We maintain a separate optimised T-Box index for our reasoning procedure. To keep the resulting knowledge-base manageable, both in size and quality, we made the following modifications to traditional reasoning procedures:

- only consider a positive fragment of OWL reasoning;
- analyse the authority of sources to counter ontology hijacking;
- use pivot identifiers instead of full materialisation of equality.

We show in our evaluation that naïve inferencing over web data leads to an explosion of materialised statements and show how to prevent this explosion through analysis the authority of data sources. We also present metrics relating to the most productive rules with regards inferencing on the Web.

Although SAOR is currently not optimised for reaching full closure, we show that our system is suitable for optimised computation of the approximate closure of a web knowledge-base w.r.t. the most commonly used RDF(S) and OWL constructs. In our evaluation, we showed that the bulk of inferencing on web data can be completed with two scans of an unsorted web-crawl.

Future work includes investigating possible distribution methods: indeed, by limiting our tool-box to file scans and sorts, our system can be implemented on multiple machines, as-is, according to known distribution methods for our foundational operations.

ACKNOWLEDGMENT

A preliminary version of this article has been accepted at ASWC 2008 (Hogan, Harth et. al. 2008). SAOR: Authoritative Reasoning for the Web. Proceedings of the 3rd Asian Semantic Web Conference (ASWC 2008). Bankok, Thailand.

Compared to that version, we have added significant material. The added contributions in this version include (i) a better formalisation of authoritative reasoning, (ii) improvements in the algorithms, and (iii) respectively updated experimental results with additional metrics on a larger dataset.

We thank the anonymous reviewers of this and related articles for their valuable feedback.

ENDNOTES

1. Throughout this article, we assume that http://www.w3.org/2002/07/owl# is the default namespace with prefix ":", i.e. we write e.g. just "`:Class`", "`:disjointWith`", etc. instead of using the commonly used `owl:` prefix. Other prefixes such as `rdf:`, `rdfs:`, `foaf:` are used as in other common documents. Moreover, we often use the common abbreviation 'a' as a convenient shortcut for `rdf:type`.
2. http://www.dajobe.org/2004/01/turtle/
3. Unlike some other rule systems for RDF, the most prominent of which being CONSTRUCT statements in SPARQL, we forbid blank nodes; i.e., we forbid existential variables in rule consequents which would require the "invention" of blank nodes.
4. http://xmlns.com/foaf/spec/index.rdf
5. Tim (now the same entity as the W3C) is asserted to be a member of the two disjoint classes: `foaf:Person` and `foaf:Organization`.
6. In (ter Horst 2005), rules using RDF collection constructs were not included (such as our rules **rdfc0,rdfc1,rdfc3*)** as they have variable antecedent-body length and, thus, can affect complexity considerations. It was informally stated that `:intersectionOf` and `:unionOf` could be supported under pD* through reduction into subclass relations; however no rules were explicitly defined and our rule **rdfc3b** could not be supported in this fashion. We support such rules here since we are not so concerned for the moment with theoretical worst-case complexity, but are more concerned with the practicalities of web-reasoning.
7. A similar example from the Web can be found at http://thesauri.cs.vu.nl/wordnet/rdfs/wordnet2b.owl.
8. In any case, as we will see in Section 3.4, our application of authoritative analysis would not allow such arbitrary third-party re-definition of core RDF(S)/OWL constructs.
9. Here, slightly abusing XML terminology by "namespace" of a URI we mean the prefix of the URI obtained from stripping off the final NCname
10. See Appendix A&B of http://www.w3.org/TR/swbp-vocab-pub/
11. Includes some RDF collection fragments which may not be part of a class description

[12] We expect that a caching on-disk index would work well considering the distribution of membership assertions for classes and properties in web data; there would be a high hit-rate for the cache.

[13] In N-Quads format: c.f. http://sw.deri.org/2008/07/n-quads/

[14] This is from incorrect use of the FOAF ontology by prominent exporters. We refer the interested reader to (Hogan, Harth et. al. 2007)

[15] For example, the document retrievable from http://pike.kw.nl/files/documents/pietzwart/RDF/PietZwart200602.owl defines super-classes/-properties for all of the FOAF vocabulary.

[16] Thirty-four such `:unionOf` class descriptions can be found in http://colab.cim3.net/file/work/SICoP/ontac/reference/ProtegeOntologies/COSMO-Versions/TopLevel06.owl; fifty-five can be found in http://lsdis.cs.uga.edu/ oldham/ontology/wsag/wsag.owl

Chapter 7.20
A Framework for Integrating the Social Web Environment in Pattern Engineering

Pankaj Kamthan
Concordia University, Canada

ABSTRACT

In the last decade, patterns have emerged as a notable problem-solving approach in various disciplines. This paper aims to address the communication requirements of the elements of pattern engineering (namely, actors, activities, and artifacts) in general and the pattern realization process in particular. To that regard, a theoretical framework using the Social Web as the medium is proposed and its implications are explored. The prospects of using the Social Web are analyzed by means of practical scenarios and concrete examples. The concerns of using the Social Web related to cost to actors, decentralization and distribution of control, and semiotic quality of representations of patterns are highlighted. The directions for future research including the use of patterns for Social Web applications, and the potential of the confluence of the Social Web and the Semantic Web for communicating the elements of pattern engineering, are briefly explored.

INTRODUCTION

The reliance on the knowledge garnered from past experience and expertise is important for any creative endeavor. A pattern is one such type of conceptually reusable knowledge (Buschmann, Henney, & Schmidt, 2007b). From their origins in urban planning and architecture in the 1970s (Alexander, Ishikawa, & Silverstein, 1977; Alexander, 1979), followed by object-oriented software design in the late 1980s and the early 1990s (Gamma et al., 1995), patterns have found applications in various domains of interest (Rising, 2000; Henninger & Corrêa, 2007). For novices, patterns are means of guidance; for experts, they are means of reference. The use of patterns has, for example, enabled the construction of high-quality distributed software architectures (Buschmann, Henney, & Schmidt, 2007a), electronic commerce applications (Kamthan & Pai, 2008), mobile interaction design (Ballard, 2007), secure systems software (Schumacher et al., 2006), use case models (Kamthan, 2009), and Web Applications (Kamthan, 2008), to name a few.

The human-centric nature of patterns has been known for some time (Coplien, 1996; Schumacher et al., 2006). For its broad acceptance and use, the knowledge in form of patterns needs to be explicably communicated to its actors.

The Social Web, or as it is more commonly referred to by the pseudonym Web 2.0 (O'Reilly, 2005; White, 2007), is the perceived evolution of the Web in a direction that is driven by 'collective intelligence' (Engelbart, 1995), realized by information technology, and characterized by user participation, openness, and network effects. The purpose of this paper is to assess the viability of the Social Web environment in serving as an ecosystem for many-to-many asynchronous and synchronous communication of the elements of pattern engineering in general and the pattern realization process in particular. For the sake of this paper, the Social Web *environment* includes Social Web technologies, applications based on those technologies, and tools for managing both.

The rest of the paper is organized as follows. The background and related work necessary for the discussion that follows is first outlined. This is followed by introduction of a theoretical framework for communicating the elements of pattern engineering via the Social Web (namely, SW4PE) that includes identifying and classifying actors of patterns, a model for the pattern realization process, and communication requirements for pattern engineering. Then, a detailed analysis of the prospects and concerns of using the Social Web for communicating the elements of pattern engineering along different dimensions is carried out. In particular, the role of 'collective intelligence' and of the technologies/applications underlying the Social Web including blogs, folksonomy, mashups, microformats, podcasting, social bookmarking, social networking, and Wikis, is highlighted. Next, challenges and directions for future research are outlined. Finally, concluding remarks are given.

BACKGROUND AND RELATED WORK

This section presents a synopsis of terminology specific to patterns and a perspective of related work. In particular, limitations of the current media towards communicating the elements of pattern engineering are highlighted.

A Terminological Overview of the Pattern Space

There is currently no standard or a reference model for terminology related to patterns. Therefore, for the definition of the members in the *pattern space*, this section relies on selected publications (Appleton, 1997; Meszaros & Doble, 1998; Buschmann, Henney, & Schmidt, 2007b) that can be considered as authoritative.

A *pattern* is defined as an empirically proven solution to a recurring problem that occurs in a particular context. There are several possible views of a pattern. From a structural viewpoint, a pattern is typically described using an ordered list of elements that are labeled as (pattern) name, author, context, problem, forces, solution, examples, and related patterns. At times, the labels may vary across community, and other (optional) elements, such as those related to *metadata*, may be included to enrich the description.

The name element of a pattern is an evocative, often a noun-phrase, metaphor reflecting the nature of the solution; the author element gives the identity of the pattern author(s); the context element provides the situation or pre-conditions within which the problem occurs; the forces element provides the constraints that are resolved to arrive at a solution; the solution element provides an abstract, general, and reusable solution to the problem and is shown to work in practice via an examples element; and the related patterns element outlines any other pattern(s) to which a pattern is related to in some way. It is this structure that makes patterns more practical in their applicability compared to other expert bodies of knowledge such as principles, guidelines (Wesson & Cowley, 2003), and heuristics.

A pattern is usually referred to by its name. In this paper, the name of a pattern is listed in uppercase in order to distinguish it from the surrounding text.

There are other members in the pattern space closely related to a pattern. An *anti-pattern* is a pattern that suggests a 'negative' solution to a given problem, and occurs when the context of the problem is not understood or the underlying forces are not optimally balanced. A *patlet* is a 'simplified' description of a pattern, providing only a short statement of the problem and solution, and does not include other elements. A *pattern thumbnail* is similar to a patlet except that it is usually accompanied with a picture of the solution. The purpose of both patlet and a pattern thumbnail is to briefly introduce a pattern (without engaging in details) so that a pattern reader can make an informed decision whether or not to read any further. This can be particularly significant when there is a large collection of patterns to select from.

It is rarely the case that a pattern exists in isolation. Indeed, a pattern is often intimately related to other patterns in many different ways. A *pattern language* is a network of patterns that are intimately related to each other by a common goal and collectively solves a larger problem than that possible by any individual pattern. The collection of patterns in a pattern language when taken together forms a 'vocabulary' that can be used by the actors for communication.

A sequential reading through the text of a lengthy pattern language may not be sufficient to gain an overall picture that is necessary for its understanding and subsequent use. A compact graphical representation can be useful in such a case. For a given pattern language, a *pattern language map* is a visual presentation of patterns and their relationships.

A *pattern management system* (PMS) is an interactive software system with responsibilities that include archiving a selected collection of patterns that could evolve (added, deleted, or modified), facilitating the discovery of those patterns via navigation or searching, and rendering those patterns on a user agent. For example, a PMS could be based on a client-server environment of the Web (Kamthan, 2008).

A *pattern realization process* (PRP) is a collection of activities and their interrelationships for specifying a pattern. The activities themselves can either be individual or social.

Finally, *pattern engineering* (PE) is a systematic and disciplined approach to the definition, subsequent use and maintenance, and interface to humans, machines, and other entities of knowledge of a member of the pattern space within the given constraints of available resources. A PRP is a part of PE.

Medium for Communicating the Elements of Pattern Engineering and the Human/Social Factors

Every means of communication requires a medium. From 1970s to about mid-1990s, patterns were essentially restricted to print medium like commercial-only books or event proceedings. According to an empirical study (Henninger & Corrêa, 2007), the print medium continues to dominate as a major channel for publishing patterns.

However, a print medium provides limited opportunities for communication. In particular, it enables only a one-to-many communication paradigm; there is no interaction; information in modalities like animation, audio, video, or three-dimensional graphics can not be communicated; there is notion of presentation, not of representation; a reuse can only be realized through citation or duplication; entities (such as books) are essentially isolated from each other; it is not possible to provide multiple views of the same information (for example, change the level of magnification) or, on-demand, present information at different levels of abstraction; and there is no support for hypertext.

In the past decade or so, the electronic (digital) medium, particularly the distributed environment of the Internet and the Web, has proved to be a useful vehicle for communicating elements of PE in different sensory modalities. The use of electronic mail (e-mail) and Internet Relay Chat (IRC) services, both of which predate the Web, has conventionally been made for communicating asynchronously and synchronously, respectively. As indicated by surveys (Deng, Kemp, & Todd, 2005; Henninger & Corrêa, 2007), mailing lists and newsgroups dedicated to patterns have spawned and various domain-specific portals/repositories for patterns, usually equipped with navigation and search mechanisms, have been established.

However, mailing lists and newsgroups provide limited capabilities for organizing patterns (Manolescu et al., 2007). Furthermore, a conventional repository is limited by one or more of the following issues: it tends to be prescriptive; it still only enables a one-to-many communication paradigm; it usually only provides an author-view of patterns where the role of a reader is that of a mere observer, not a contributor; and, in general, any human or social relationships in PE are not always made explicit. This is prohibitive to the advancement of patterns and could potentially undermine their significance.

To alleviate some of these issues, human and social aspects of the PRP and subsequent deployment, in addition to technical considerations, is necessary. There have been some partial efforts in that direction such as the use of Wikis (Weiss & Birukou, 2007) but an in-depth analysis has not been carried out. This lends one of the motivations for this paper.

A FRAMEWORK FOR COMMUNICATING THE ELEMENTS OF PATTERN ENGINEERING USING THE SOCIAL WEB ENVIRONMENT

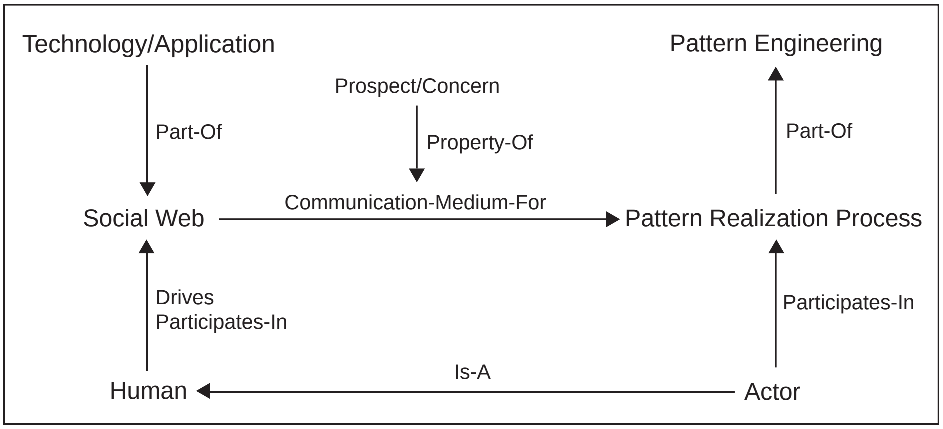
This section posits SW4PE, a framework for communicating the elements of PE via the Social Web illustrated in Figure 1. In the forthcoming sections, the actors of patterns are identified and classified, the details of the PRP are specified, the actor-specific requirements for communicating the elements of PE are outlined and, based on these, the prospects/concerns of integrating the Social Web technologies/applications in PE in general and PRP in particular are discussed in detail.

A Model for Actors of Patterns

According to the CLEAR TARGET AUDIENCE pattern (Meszaros & Doble, 1998) and the CONSISTENT "WHO" pattern (Harrison, 2003), the external entities to which a pattern is being communicated need to be recognized. An *actor* is a person who has interest in a pattern for some purpose. Based upon their *roles*, the possible actors of patterns can be identified and classified as follows:

- **Producer:** *Pattern Author* (responsible for authoring a pattern), *Pattern Shepherd* (responsible for inspection and feedback on a pattern), *Pattern Writers' Workshop Participant* (responsible for inspection and feedback on a pattern), *Pattern Engineer* (responsible for providing means for representation and presentation of a pattern), and *Pattern Administrator* (responsible for maintenance and management of patterns).
- **Consumer:** *Pattern Reader* (target for perceiving a pattern) and *Pattern User* (target for using a pattern).

Figure 1. A high-level view of SW4PE



The actor classification scheme has a few properties. In it, the actors are not necessarily mutually exclusive. For example, there is a generalization-specialization relationship between a pattern reader and a pattern shepherd and the same between a pattern reader and a pattern user; however, the converse in both cases is not necessarily the case. The same person can also take upon different roles, and the same role can be taken upon by different persons. For example, a person casually reading a pattern plays the role of a pattern reader but given the write permission can (at least in part) play the role of a pattern administrator. The Social Web has made the boundaries among actors increasingly fuzzy as a professional pattern consumer can become a voluntary pattern co-producer, or a pattern 'prosumer' (Shuen, 2008).

Remarks

The actor classification scheme can be granularized further if needed. For example, a pattern reader and a pattern user could both be categorized further into *novice* and *expert*, or into *putative*, *potential*, or *future*. Also, pattern user could be labeled as a secondary actor, while all other actors as primary actors.

The actor classification scheme can also be extended. For example, a pattern reader could be generalized to a pattern percipient. A means of creating a taxonomy of actors for a general software system is available (Alexander, 2005), the discussion of which is beyond the scope of this paper.

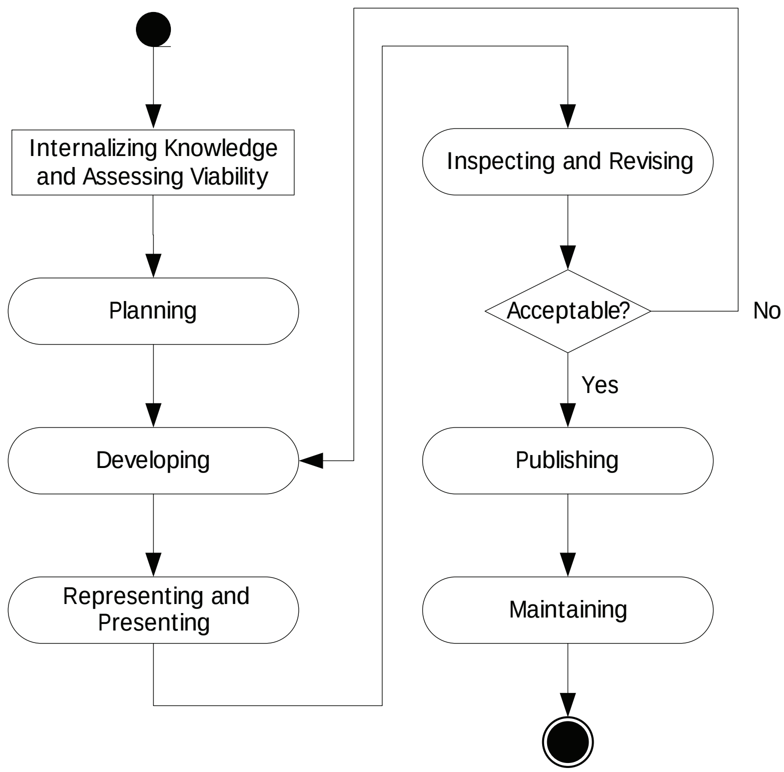
A Model for a Human-Centric and Evolutionary Pattern Realization Process

The PRP is an actor-centric, iterative, and incremental process, the resulting product of which is a pattern. A *workflow* of PRP is a high level organization unit that consists of one or more activities. As shown in Figure 2, there are a number of workflows in PRP, including (1) *planning*, (2) *developing*, (3) *representing and presenting*, (4) *inspecting and revising*, (5) *publishing*, and (6) *maintaining*. These are prefixed by (0) *internalizing knowledge and assessing viability*, which is a prerequisite to the workflows that follow.

[0]. Internalizing Knowledge and Assessing Viability

The two recommended approaches for acquiring internal knowledge are *individual* and

Figure 2. The sequence of workflows in a pattern realization process



sociological. In an individual approach, there is a single pattern author who relies on personal experiences *and* extrospections (observations) based on others' experiences; in a sociological approach, there are multiple pattern authors relying on each other's experiences.

For the sake of discussion, consider the individual approach. It is assumed in this paper that practice involves action (doing). The practice over a period of time by a person of repeatedly solving a problem in some domain leads to experiences. Among other factors, the ensemble of the experiences themselves and of the retrospective after each experience (and perhaps extrospections based on others' experiences), lead to insight. The experiences also lead to acquirement of skill. It is then insight *and* skill together that form expertise. The a posteriori, situated, and experiential knowledge internalized by the person is either implicit or tacit. The person may voluntarily decide to share the implicit knowledge with others. For that, the implicit knowledge needs to be externalized (articulated) to explicit knowledge. At that point, the person takes upon the role of a (potential) pattern author.

Based on the expertise and research of existing pattern base, the pattern author determines the viability of proposing a 'new' pattern (also known as the *proto-pattern*) to the pattern community at-large (including target pattern readers and potential pattern users). As part of this workflow, the pattern author also checks for the existence of patterns that may be similar or variants of the one being proposed. This workflow concludes with a favorable decision to proceed with the definition of a proto-pattern.

[1]. Planning

In order for the PRP to be productive, the definition of the proto-pattern requires appropriate planning by the pattern author(s). The planning needs to include an assessment of the availability of resources including time, effort, expert body of knowledge, and tools. In case of multiple pattern authors, schedules for meetings also need to be decided upon.

There is a cost factor associated with the PRP. In particular, if the pattern author seeks a 'formal' analysis of the proto-pattern, there is cost involved in traveling to the Pattern Languages of Programming (PLoP) 'family' of conferences. There can perhaps also be ancillary cost related to publishing and administering the proto-pattern. The exceptions to this are the voluntary time and effort of the pattern authors and pattern shepherds.

There are a few non-commercial resources at the pattern author's disposal to assist in the PRP. These include expert bodies of knowledge like guidelines (Buschmann, Henney, & Schmidt, 2007b) and patterns (Meszaros & Doble, 1998; Harrison, 2003) for describing patterns, and patterns for shepherding (Harrison, 2000) and Writers' Workshops (Coplien, 2000). There are also tools for representing and presenting the patterns, the discussion of which is delegated to later sections.

[2]. Developing

For the purpose of referencing, the pattern author assigns an evocative name to the proto-pattern. From an analysis of the given information, the pattern author then abstracts the problem and, guided by previous personal experiences and extrospections based on others' experiences from [0], explicitly places the problem in a specific context that reflects the scope of the problem.

Next, a general and (conceptually) reusable solution for the problem needs to be devised. This is achieved via abstraction of instances of the solution from personal experiences and extrospections based on others' experiences from [1]. The solution describes both the process *and* the thing (created by the process). The purpose of the process aspect of the solution is pedagogy. It is likely that the problem has more than one solution, and that each solution has its own advantages and disadvantages. The 'best' solution is chosen based on an optimal balance (or equilibrium) of forces (constraints), which are usually the desirable quality attributes of the solution (Lea, 1994). From an examination of previous work, it appears that the means of achieving this balance are not given.

Since even the best solution is not absolute, the pattern author examines the implications (consequences) of applying the solution. The consequences could include forces that are not entirely resolved as well as new forces that may arise. This may lead to the need for other pattern(s), which is the inception of a pattern language.

The solution proposed by the proto-pattern must be generative (Lea, 1994), that is, it must be demonstrably proven to work. Therefore, based on the 'rule of three' (Meszaros & Doble, 1998), the pattern author elicits three solution instances or examples that best demonstrate the feasibility of the proposed solution. The examples could possibly be from earlier personal experiences and extrospections based on others' experiences from [0]. However, since the proto-pattern is based on empirical knowledge, it is prone to subjectivity. Therefore, to lend some degree of objectivity, these examples should not exclusively be internal, that is, they should not be all from the pattern author's personal experiences. In other words, there must be at least one external example.

Finally, the proto-pattern is placed in its social context. To do that, related patterns (if any) along with their relationships to the proto-pattern are listed.

[3]. Representing and Presenting

In order to become explicit, the information in [2] needs a suitable means of representation. A representation can subsequently be presented in one or more ways, in one or more sensory modalities, to make it perceptible to an actor.

In this workflow, the pattern author selects one of the available means for representing and presenting the proto-pattern (that are made possible by a pattern engineer), keeping the needs of the readership (Meszaros & Doble, 1998; Harrison, 2003) into consideration. The possible means for representing and presenting a proto-pattern can vary across the spectrum of formality (informal, semi-formal, formal), modes (text, graphics), open/closed technology, and so on.

For example, proto-patterns (and even an entire proto-pattern language) may be represented (Kamthan & Pai, 2006a) in the Extensible Markup Language (XML) and, depending on the target device, subsequently presented in one of the profiles of the Extensible HyperText Markup Language (XHTML) that is targeted for the Web or in the Portable Document Format (PDF) that is targeted for printing. This marks the end of the first iteration of the PRP.

[4]. Inspecting and Revising

The proto-pattern may go through an informal inspection (a non-anonymous, highly recommended but optional, review process) to evaluate the characteristics of the proto-pattern.

The prime example of inspection includes submission of the proto-pattern to one of the members of the PLoP 'family' of conferences, which leads to shepherding (which is one-on-one mentoring of the author by another person, namely the pattern shepherd, who is familiar with the underlying domain and is experienced in describing patterns) followed by participation in a Writers' Workshop (which is a face-to-face structured peer review process involving domain experts). The inspection may lead to a few iterations of the proto-pattern and thereby a re-visitation of [2] and [3]. At the end of the inspection, the proto-pattern may reach the candidacy of a pattern.

The pattern author, individually or otherwise as a result of the inspection, may associate a rating reflecting the confidence or maturity level of the pattern. Before publication, the pattern author may also optionally include metadata information related to configuration management, copyright/licensing, and so on, in the description of the pattern.

[5]. Publishing

Up until now, the pattern is limited to internal consumption. In order for the pattern to reach a broader community (beyond the pattern author(s), pattern shepherd, and participants of the Writers' Workshop), it needs to be published in a public environment.

The pattern is published in some (usually print and/or electronic) medium that is deemed reachable to the patterns community. The Web in general and the Social Web in particular is one candidate medium for publication of patterns. For example, a Web Application for patterns could be developed in a systematic manner (Kamthan, 2008) that archives and serves desirable patterns.

[6]. Maintaining

If needed, a pattern administrator carries out corrective and/or adaptive maintenance of pattern(s) on a timely basis. Furthermore, these pattern(s) may also be integrated (into a larger collection) and organized (classified and indexed) in some way. This concludes the conventional PRP from the viewpoint of the pattern producers.

A pattern, once published, does not get 'retired' or 'terminated' (in the sense of hardware or software systems). However, for various reasons, it may lose support and go out of use.

Remarks

A few remarks concerning PRP are in order. From the description of PRP, it is evident that PRP is non-linear and its workflows are not necessarily mutually exclusive. PRP also relies on human creativity and can not be completely automated. In some ways, PRP is similar to agile software development methodologies and open source software development processes but it is not as rigorous or formal. There has traditionally been modest involvement (if any) of the pattern consumers in PRP. This changes significantly by the introduction of the Social Web as a medium in the PRP.

A multidisciplinary, interdisciplinary, and participatory methodology called Identification-Development-Refinement (IDR) for realizing interaction design patterns has been proposed previously (Winters & Mor, 2008). However, IDR does not precisely identify actors or provide details of their involvement, rejects shepherding, and its steps are subsumed by that of PRP.

Actor-Specific Requirements for Communicating the Elements of Pattern Engineering

This section lists computing environment-, domain-, and technology-independent requirements for communicating the elements of PE driven by the needs of the actors. These informally collated requirements are identified by the prefix [PE-CR-n], n = 1, 2, 3, 4, and stated as follows:

- **[PE-CR-1]** It should be possible for a pattern author to readily describe a proto-pattern; it should also be straightforward for a pattern shepherd to readily inspect and provide feedback on it (in proximity as well as remotely). In general, a pattern author and a pattern shepherd should be able to collaborate and share a proto-pattern.
- **[PE-CR-2]** It should be possible for a pattern engineer to provide a means to represent and present proto-patterns.
- **[PE-CR-3]** It should be possible for a pattern administrator to manage (including store, retrieve, process (manipulate, transform), modify, and delete) a collection of patterns with minimal effort.
- **[PE-CR-4]** It should be relatively easy for a pattern reader (and a potential pattern user) to be able to locate, read, and understand a pattern and, with appropriate permissions, be able to distribute the pattern. It should be possible for a pattern reader to contact the pattern author and the pattern administrator.

These requirements serve as a guide for the rest of the paper. The use of qualitative terms in the statements [PE-CR-1] – [PE-CR-4] is intentional: their quantification is possible but is beyond the scope of this paper. In the following, symbols [+PE-CR-n] and [–PE-CR-n], n = 1, 2, 3, 4, are used to respectively denote strong and weak conformance to the corresponding requirement.

Communicating Patterns using the Social Web Environment

The Social Web has recently emerged as a perceived extension of the current Web that fosters ‘collective intelligence’ (Engelbart, 1995) and further decentralization. The notion of the apparent ‘humanization’ and ‘socialization’ of the Web is not new and dates back to the early days of the Web. Indeed, amazon.com and eBay are classical exemplars of consumer participation that introduced product review/recommendation and feedback, respectively. The notion of decentralization also has its predecessor in file sharing via Peer-to-Peer (P2P) computing.

However, it appears that there are three primary factors that have brought the vision of the Social Web to a mainstream realization: (1) it enables a many-to-many communication paradigm; (2) the maturation of the underlying technological infrastructure and the availability of its implementations as open source, and (3) the awareness, followed by immense interest and large-scale participation, by the public in general.

This paper advocates retaining the advantages that the Web offers towards communicating the elements of PE and assessing the viability of the Social Web in extending those advantages. The Social Web provides the medium in which human-to-machine-to-human communication takes place to realize human-to-human communication.

Scope of SW4PE: Open Problems in Patterns—Beyond Information Technology and the Web

There are certain impediments that the actors currently face in their dealings with patterns. In the future, it is theoretically possible that some of the issues, like the existence of a meta-index of repositories (Manolescu et al., 2007) or means for more precise search/retrieval might be addressed and even get resolved by technological means within the realm of the Web and its extensions.

Still, there are other pressing issues, like existence of a coordinating body for patterns, standardization of terminology related to pattern engineering body of knowledge (PEBOK), standardization of representations of patterns, or making all patterns as open/freely available content, that are obstacles to pervasiveness of patterns. These issues naturally constrain SW4PE, and are likely to remain beyond the scope of the Web and its foreseeable extensions.

AN ASSESSMENT OF THE PROSPECTS AND CONCERNS FOR COMMUNICATING THE ELEMENTS OF PATTERN ENGINEERING USING THE SOCIAL WEB ENVIRONMENT

In this section, based on the background set forth in the previous sections, the prospects as well as the concerns in deploying the Social Web are each assessed along certain dimensions.

Prospects for Communicating the Elements of Pattern Engineering via the Social Web

There are certain aspects of patterns that make them a natural fit within the environment of Social Web. In this section, the potential of the Social Web for communicating the elements of PE is explored along the lines of [PE-CR-1] – [PE-CR-4] and, to that regard, specific examples are provided.

Collaborating and Sharing

There is need for collaboration and sharing during the different workflows of the PRP. A pattern reflects *shared* understanding of a domain, and can be viewed as a shared resource or 'commons' (Hess & Ostrom, 2007). In the PRP, the transition of a proto-pattern to the status of a pattern inevitably involves collaboration during shepherding and during Writers' Workshops. Also, a pattern author needs to be cognizant and be sensitive to pattern readers' concerns. The Social Web lends various opportunities for collaboration and sharing, which we consider next.

Collaborative Researching

The Web has become an indispensable source for researching for information, and the same holds for elicitation of domain knowledge (such as elicitation of pattern instances) during the PRP. There are Social Web applications like Google Notebook and Microsoft OneNote that allow one to attach notes to and clip text, graphics, and links during researching. These 'notebooks' can be saved, and can subsequently be used for collaboration and sharing with others. Furthermore, the 'notebooks' in Google Notebook can be exported to Google Docs.

Social Scheduling

A face-to-face meeting, whether it is for sociological approach to elicitation of domain knowledge or for Writers' Workshop, requires scheduling. A schedule that is agreeable to all, particularly as the number of persons involved increases, can become difficult to manage. The use of Social Web applications that facilitate calendar sharing (such as the Google Calendar) can reduce some of the tedium involved in scheduling a meeting agenda.

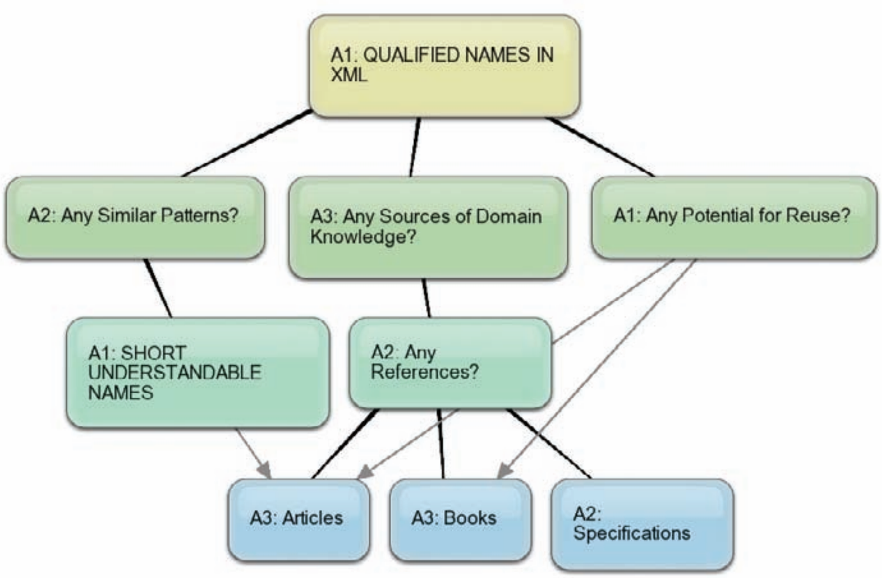
Brainstorming

Brainstorming is implicit to various activities in the PRP. For example, in a sociological approach to elicitation of domain knowledge, the authors often engage in brainstorming (for collectively organizing their thoughts and recall, for collaborative decision making, and so on). The same idea applies to the dynamics of shepherding.

One way to brainstorm is through visualization, and mind mapping is a graphically-oriented approach to realize it. A mind map is a graph where nodes represent sub-ideas (or sub-goals or sub-tasks) at different levels of granularity and vertices represent 'semantic' relationships, all of which are arranged radially around a central idea (or goal or task, respectively). The pattern authors can share these mind maps over the Web and, depending on the permissions, read and/or edit others' maps.

Figure 3 illustrates a snapshot in time (work in progress) of a mind map using the bubbl.us tool

Figure 3. An example of a partial mind map reflecting a brainstorming session on the viability of the 'new' QUALIFIED NAMES IN XML pattern



(http://www.bubbl.us/). In it, three authors, namely A1, A2, and A3 are in a brainstorming session on the viability of a proposed pattern. The 'bubbles' reflect respective inputs by pattern authors.

Collaborative Authoring

The Social Web presents a suitable environment for collaborative authoring of patterns using various means including Google Docs and Wiki. The concept of Wiki (Leuf & Cunningham, 2001) was invented in the mid-1990s as a group communication utility. It allowed open editing of information (like patterns) as well as the organization of the contributions and, with various enhancements, continues to serve well in that vein (Weiss & Birukou, 2007). A properly administered Wiki assists pattern authors, pattern shepherds, and pattern readers. Indeed, barring certain reservations, a Wiki environment enables a person to play the dual role of a pattern reader and a pattern administrator.

There are several, opens source flavors of Wiki available today addressing different target groups and organizational needs. Most flavors of Wiki, including MediaWiki and TinyWiki, can be easily acquired, installed, and administered under commonly-deployed computing platforms (Ebersbach, Glaser, & Heigl, 2006). For example, Asynchronous JavaScript and XML (AJAX) Patterns (http://ajaxpatterns.org/) and Perl Design Patterns (http://perldesignpatterns.com/) are collections of patterns based on MediaWiki and TinyWiki, respectively.

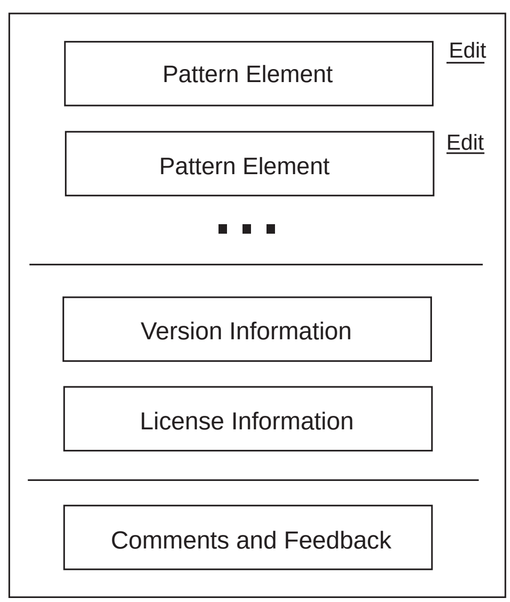
Figure 4 presents a simplified view of the description of a pattern within the Wiki environment. The mandatory elements of a pattern can be presented where they can be progressively disclosed (Lieberman, 2007) and edited; the details of history of the document can be automatically highlighted through version information; licensing terms can be made explicit; and pattern reader's feedback can be solicited and included. The figure could, for example, be extended by the addition of a block for the table of contents (in case the document is lengthy).

It is not absolutely necessary (although it may be relatively easier) to deploy Social Web technologies/applications for realizing collaboration. The conventional technologies/applications that have found success on the Web such as the Personal Hypertext Preprocessor (PHP) can be used to achieve similar effect as a Wiki. For example, a collection of patterns for 'living spaces' (http://architypes.net/patterns.php) is built from collaboration between architects, interior designers, and photographers.

Syndication

Every so often pattern consumers need to keep track of several resources on patterns, including announcements of new patterns or modifications of the existing ones, availability of relevant books or podcasts, and so on. However, individually and

Figure 4. A glimpse into an abstract, partial view of the description of a pattern within the Wiki environment



somewhat arbitrarily visiting each Web Site of interest can be inconvenient and time consuming. The subscription to periodically refreshable news feeds helps ameliorate this issue.

Syndication is a type of metadata implemented in form of channels that point to relevant resources on a topic that the pattern readers can subscribe to. There are a variety of syndication technologies of which Really Simply Syndication (RSS) and Atom are beginning to find broad support in conventional user agents and news feed readers.

For example, the following RSS markup fragment represents news for a specific day from a single channel:

```
<?xml version="1.0" encoding="UTF-8"?>
<rss version="2.0">
  <channel>
     <title>Pedagogical Patterns Channel</
     title>
    <link>http://www.pattern.ca/</link>
    <description>
     This is a channel for news on patterns
     related to teaching and learning
       in the classroom.
    </description>
    <item>
        <title>News for January 15, 2008</
     title>
   <link>http://www.pattern.ca/2008/01/15/</
     link>
       <description>
        The interview of the author of the
     recently published book titled
        Patterns in the Classroom is avail-
     able as a podcast ...
       </description>
    </item>
  </channel>
</rss>
```

It could, for instance, be stored in a file named `PedagogicalPatterns.rss` and linked from a place that pattern readers could readily discover.

Social Bookmarking

Bookmarking has traditionally been one of the most common ways of remembering the resources of interest visited while browsing on the Web. However, these bookmarks reside on the user's computer and are not accessible by other devices (and therefore are not shareable).

Social bookmarking enables management (for example, storage, organization, search, and sharing) of booksmarks residing remotely at third-party services. By unifying their knowledge base, social bookmarking can help pattern authors and pattern shepherds communicate more effectively during the PRP. By expending modest effort, it can also help pattern consumers share links to resources (including desirable patterns) amid themselves. The notion of social bookmarking was pioneered by itlist.com in the mid-1990s and brought into mainstream around 2003 by del.icio.us. Since then other social bookmarking services like Google Bookmarks have spawned.

Organizing and Social Networking

It was claimed more than a decade ago that "finding patterns is much easier than describing them" (Gamma et al., 1995). On the Web, one could locate a pattern one of the following three ways: (1) directly using the (known) address where a pattern resides, (2) by navigating to the address, or (3) by searching through a collection. However, the rapid growth (Henninger & Corrêa, 2007) of the number of patterns and pattern languages has made the task of locating desirable patterns increasingly challenging for the pattern readers. Still, by participating in the Social Web, the pattern consumers can help one another (and indirectly help the pattern producers) in somewhat easing the task of locating desirable patterns, and folksonomy is one way to do that.

Folksonomy

A suitable organization of patterns is critical for locating desirable patterns. However, the search for a suitable organizing scheme for locating desirable patterns continues to remain a persistent and elusive problem (Hafiz, Adamczyk, & Johnson, 2007).

A crucial aspect of organization is classification. There is no universal scheme for classifying patterns: a pattern placed in one category by its author(s) can reappear as belonging to a different category in a different pattern language by another set of author(s). For example, the MODEL-VIEW-CONTROLLER (MVC) pattern (Buschmann, Henney, & Schmidt, 2007a) can be classified in multiple different ways, including categories that are not envisioned by its original author(s) but are considered relevant by its pattern readers and pattern users. This 'post-publication' faceted classification of a pattern is possible by social annotation, specifically via the notion of folksonomy or social tagging (Smith, 2008).

Folksonomy enables pattern readers to associate with a resource words or phrases that they deem meaningful, relevant, and significant in describing the resource. By doing so, there is an implicit assumption that other (new) pattern readers will share and benefit from this understanding of the resource.

Folksonomy can be realized in several different ways. For instance, the semantics of the XHTML documents can be extended using certain mechanisms within the div, span, and class elements, and id and rel attributes. Microformats (Allsopp, 2007) are an effort to standardize the conventions for using these extension mechanisms. In XHTML, the attribute-value pair rel="tag" can be used to indicate that the resource that has been linked-to acts as a tag for the current context. For example, to tag an XHTML document describing the MVC pattern with 'Distributed Computing,' markup such as Distributed Computing could be used.

A collection of tags can lead to the formation of a tag cloud. (There are some resemblances between a tag cloud and the classical Web concepts of image map and site map.) A tag cloud is set of related tags with associated weights that represent frequency of use of each tag. The tags within a tag cloud are usually ordered lexicographically and the frequency of use of each tag is illustrated by visual cues such as distinct font color and size. It is preferable to use a style sheet language such as the Cascading Style Sheets (CSS) for associating presentation semantics with tags.

The 'human element' of the Social Web—as personified by mutual collaboration among the actors in locating desirable patterns through navigation—can be realized in the following manner: by proper organization of tags and representation of weights in a tag cloud, pattern administrators and pattern engineers can help the pattern readers, and by a careful selection of tags, pattern readers can help each other.

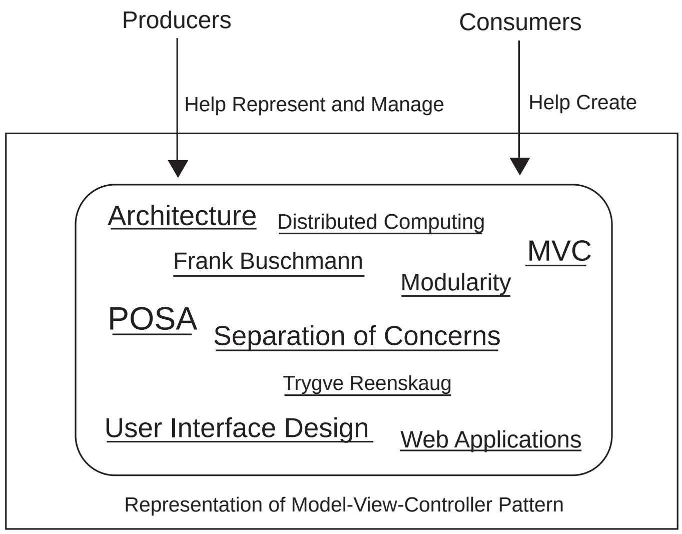
Figure 5 shows a tag cloud for the MVC pattern. It can be noted that the tags are not all of the same type: while some are about things, others are about people. For example, Modularity is a software engineering principle; POSA is the acronym for Patterns for Software Architecture; and Trygve Reenskaug is the person who is ascribed for first introducing MVC, and the tag could, for instance, link to a resource that acknowledges this.

The above idea can be extended to tagging a pattern language map that is dynamically-generated and expressed in a vector graphical language such as the Scalable Vector Graphics (SVG).

Social Networking

There are plenty of opportunities for social networking (Freeman, 2004) during and after the PRP. A variety of different types of social relationships can exist among the actors including pattern author-to-pattern author, pattern author-

Figure 5. A tag cloud embedded in the abstract representation of the MODEL-VIEW-CONTROLLER pattern



to-pattern shepherd, and pattern reader-to-pattern reader that can be made explicit.

The XHTML Friends Network (XFN) is a specification for explicitly indicating social networking relationships using `rel` attribute values in XHTML on blogroll links. For example, XFN values can be added to the `rel` attribute by a pattern author to indicate that John Smith is the shepherd, is a colleague, and is someone the author has met, using the following markup:

```
<ul>
  <li>
    <a href="http://john.smith.ca/"
        rel="colleague met shepherd">John
     Smith</a>
  </li>
</ul>
```

The social networking relationships expressed in XFN could be exploited by programs like bloggers, search engines, or spiders.

Publishing

The authors of patterns and pattern languages publish their work at the end of the process. In doing so, there are several issues involved. The representation and presentation of a published pattern can often be heterogeneous in nature, involving the use of different modes of information (text, graphics, source code, and so on). For instance, the solution of a pattern, particularly that is structurally-oriented, is usually accompanied with a picture illustrating the solution in an abstract manner or of its instances (examples). Any publishing also needs to take into account that some information can be reused and repeated at multiple places, and it needs to evolve independently for an effective maintenance. For example, the picture in a solution may also be a part of a pattern thumbnail. It is also possible that the author may not have complete technical control or legal rights to physically include some of the desirable information but nevertheless still needs to point to it. From a Social Web viewpoint, these considerations, if appropriately carried out, are suitable for a mashup.

Mashups

A mashup aggregates and reuses information from multiple sources. This is accomplished via some means such as a transclusion (Nelson, 1982), which is an on-demand inclusion of one resource into another via hyperlinking and/or a programmatic mechanism like an Enterprise Mashup Service (EMS), which is a Web Service based on the Service-Oriented Architecture (SOA). It then presents information in a federated manner that is transparent to a pattern reader.

Figure 6 illustrates an abstract construction of a pattern mashup in which author information, picture of an example, and licensing terms are 'transcluded' from external sources.

Both pattern authors and pattern readers (using, say, iGoogle) can benefit from mashups. For example, the description of a user interface pattern could reside on one server and, after receiving appropriate permissions, 'transclude' a picture depicting a solution instance from another server (like that of Flickr). As another example, the author can indicate that the pattern is licensed under the Creative Commons 3.0 Attribution Required License by including the markup `<a href="http://creativecommons.org/licenses/by/3.0/" rel="license">CC by 3.0</a>` in an XHTML document.

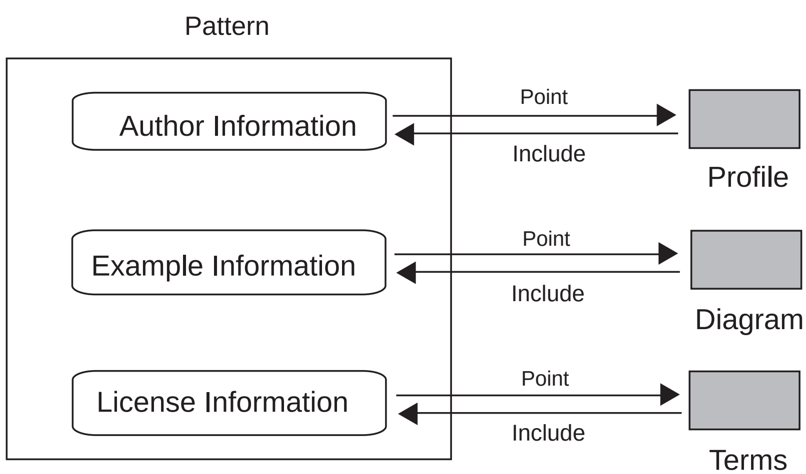
Deliberating, Educating, and Outreaching

It is the responsibility of the pattern authors to make a considerate effort to reach their audience of pattern consumers and, in doing so, use any means available to them. Being able to publish is only one aspect of communicating the elements of PE: it is also indirect, passive, and static, where the human side of patterns is less apparent. The Social Web presents an array of possibilities for direct, active, and dynamic means for communicating the elements of PE through a judicious use of media outlets. In particular, blogging and podcasting are asynchronous and synchronous means of communicating, respectively.

Blogging

A blog is an outlet for anybody to publicly express opinion, in writing, on just about any subject. In

Figure 6. A pattern mashup that points to and includes three different external sources



side bar of a personal blog, a blogger can provide a list of other blogs (or a blogroll).

There are a few benefits of blogging for the actors of patterns. Blogging gives pattern authors to respond to concerns of pattern consumers in an informal environment, inform others of their scholarly activities related to patterns (like relevant presentations at events), or state their current position about the (mis)use of patterns. For example, for the past few years, Grady Booch has been blogging about issues related to the Handbook for Software Architecture (http://www.booch.com/architecture/), which is one of the largest collections of patterns on software architecture. Blogging also gives pattern readers an opportunity to ask questions, and make their agreements and disagreements known in a public forum. For example, the Software Patterns Blog (http://pattern.ijop.org/) has been used by Mohamed Fayad to express concerns regarding current obstacles to learning and selecting patterns.

Podcasting

Podcasting provides an avenue to the pattern community for education and outreach by means of audio and video. For example, YouTube (http://www.youtube.com/results?search_query=Patterns) provides a platform for authors to post their presentations from events or other forms of media supporting patterns for a general audience without having to provide the service themselves. The pattern readers can provide comments on the videos, rate the videos, and add the videos to their list of social bookmarks.

As another example, the Software Engineering Radio (http://www.se-radio.net/) offers podcasts for interviews on software engineering related topics in general (Rech, 2007) and software patterns in particular. These interviews provide an opportunity for the authors to *converse* about patterns: demonstrate the patterns process by answering questions related to their experience in the domain, including successes and failures; draw attention to the history of patterns they elicited; mention the reasoning behind the selection of a means of representation or choice of examples; and so on.

Table 1 presents a summary of the key activities in PE and supporting concepts/activities corresponding to the Social Web discussed in this section.

Concerns of Communicating the Elements of Pattern Engineering via the Social Web

The integration of patterns within the Social Web is not absolute and has its share of shortcomings. In this section, the scope and limitations of the Social Web for communicating the elements of PE is examined and in doing so specific examples are provided.

Cost to Actors

The issue of cost impacts all actors. The increase in the number of mature, open source implementations of the technologies underlying the Social Web has contributed to control of development costs and thereby to the reduction of entry barrier for aspiring pattern producers. There is still the non-trivial cost of time and effort in learning, especially due to the fact that there is currently no single provider of these implementations and that the interaction (including the user interface functionality) varies tremendously from one application to another.

However, for pattern consumers, the technological infrastructure of the Social Web remains largely exclusive: for optimal operation, it assumes high-speed Internet connection, state-of-the-art operating systems, and latest user agents with up-to-date capabilities on the client-side. This is not all free-of-cost for personal use. In general, ‘Rich Internet Applications’ of the Social Web

• Mentoring a Pattern Author, Pattern Reader, or Pattern User	• Blogging • Podcasting • Responding to Feedback
• Maintaining a Pattern	• Social Web Application
• Interfacing a Pattern with Other Entities of Knowledge and Artifacts	• Social Web Application

are resource-intensive. For example, the mashups in which aggregation of information takes place on the client-side expect hardware and software capabilities that a pattern consumer may not have. As another example, the Software Engineering Radio podcasts are currently not streamed but are available only as download at file sizes that could be prohibitive to those on low bandwidth.

The issue of hardware and network cost is not perennial. If past statistical trends are any indicators, then it is likely to subside with time. The cost of hardware necessary for creating Social Web applications (like computers with fast processor speeds, and large storage space and memory; digital cameras; audio recorders; and so on) has been on decline in the past few years, and reflect a market trend that is expected to continue. The same applies to cost of Internet service. However, it also needs to be noted that the original vision of the Web is yet to be realized: a large segment of the world population does not (still) have access to the Internet in general (Press, 2004) and the Web in particular.

Decentralization and Distribution of Control

The technologies underlying the Social Web can be disruptive: they require change and, in some cases, radical departure from conventional approaches. For instance, the Social Web is not meant for pattern authors working individually in isolation.

Any form of multi-node interaction over a distributed network where a node could be either a human or a machine (like real-time collaboration among author and shepherd, resource sharing, or mashup) creates an indirection. Its success is based on the assumption that it works like a symphony: *all* the nodes involved are available, are in unison, interaction among them is transparent and timely, and so on. The past experience with the Web has shown that the relationship between the probability of success and the number of nodes is not linear (the former can decrease as the latter increases).

The 'transfer' of even some of the traditional control from server-side to client-side has its side-effects that need to be balanced. For example, the exposure of the PRP to the Social Web may lead to a perception by the pattern readers that a pattern is never 'complete' but in a 'perpetual beta' state, which contradicts the characteristic of 'timelessness' (Alexander, 1979) of a pattern. The transfer of control also faces a classical dilemma. For example, moderating feedback by retaining only complimentary messages from pattern consumers or time-delimiting the feedback could be perceived as bias on part of pattern producers, which is against the spirit of openness of the Social Web. In contrast, it is not automatic that all unfiltered feedback driven by 'citizen journalism' or 'user-generated content' contributes to enriching the description of a pattern, and therefore some degree of moderation is necessary.

In spite of several possible uses, the flexibility of blogs and Wikis comes with a price: they are known for 'noise' (including impertinent information), 'casual' writing (due to the presence of phonetic, 1337 style of writing, and frequent spelling and/or grammatical errors), and 'editing wars' (discussions that have morphed into endless debates that put personal interest before that of a pattern reader). These, however, can be attributed to human usage rather than to inherent limitations of the underlying technology. In any case, this impacts the quality of the description of a pattern, and is not favorable to either a pattern administrator ([–PE-CR-3]) or to a pattern reader ([–PE-CR-4]). A partial solution to this issue could be to (1) separation of the description of a pattern as provided by the pattern author from any annotations (which should be clearly labeled and managed as such), and (2) provision of multiple views of a pattern, including the option to suppress any annotations, to a pattern reader.

Folksonomy (as opposed to taxonomy) is an uncontrolled vocabulary, and the lack of terminological control can have linguistic implications due to synonymy, homonymy, and polysemy. In particular, classical issues associated with the natural language use of acronyms can surface. It is not automatic that all tags that are created by pattern consumers may be relevant to the context. For example, MVC has other known expansions like Marriott Vacation Club, the Missouri Valley Conference, and the Motor Vehicle Commission that are irrelevant to the notion of a pattern as discussed in this paper. Similarly, the tag 'Architecture' in the civil engineering sense is not relevant to the MVC pattern. Therefore, once again, to add long-term value, the tags associated with the description of a pattern need to be monitored and moderated.

Semiotic Quality of Representations of Patterns

The theory of semiotics is the field of study of signs in which the communication itself is viewed as interchange of signs. It is known that a pattern can be viewed as a second-order sign of a semiotic system (Buschmann, Henney, & Schmidt, 2007b). It is possible for a sign to have one or more representations.

From a semiotic viewpoint (Stamper, 1992), the quality of the representation of a pattern (and a member of the pattern space in general) can be viewed on six interrelated levels: physical, empirical, syntactic, semantic, pragmatic, and social. This paper focuses on the last two levels. Then, inspired by conventional quality modeling (Fenton & Pfleeger, 1997) and by [PE-CR-1] – [PE-CR-4], pragmatic and social levels can be decomposed further. The desirable pragmatic and social quality attributes of concern to a pattern producer include comprehensibility, legality, and maintainability, while the desirable pragmatic and social quality attributes of concern to a pattern consumer include accessibility, comprehensibility, credibility, performance, readability, reliability, and usability.

The quality of representations of a growing number of patterns and pattern languages on the Web is a concern. In recent years, various accessibility, performance, reliability, and usability issues with patterns and pattern languages made available on the Web have been reported (Dennis & Snow, 2006; Segerståhl & Jokela, 2006; Manolescu et al., 2007). The evaluations (Deng, Kemp, & Todd, 2005) of certain collections of patterns (Gaffar et al., 2003) lead to questions of the credibility of these collections and for which there are no trivial answers.

The technologies/applications underlying the Social Web do not by themselves contribute towards the improvement of many of the aforementioned quality attributes of representations of patterns. In fact, in some cases they can potentially lead to a detriment. For example, let use consider the case of accessibility and legality. The misuse of microformats by overriding the semantics of XHTML attributes or real-time applications based on AJAX that are exclusively visually-driven, mouse-input-only, can be unfavorable to accessibility (Cooper, 2007). The use of fixed fonts and certain colors can make the tags/tag clouds inaccessible to those with certain forms of visual disability. A similar argument holds for podcasts. XFN graphs can become unreadable as the number of nodes and vertices increase. Furthermore, this situation only gets exacerbated with the use of mobile devices to access the Social Web.

The rise of the Social Web has amplified the classical struggle between liberty and legality. The term 'free' in the notion of 'freely sharing' on the Social Web (analogous to the open source movement) stands for freedom. As the same time, the preservation of rights of the creators of digital work is an ongoing challenge in a distributed environment where laws (if any) can vary across jurisdictions, and patterns are no exception. The use of pattern mashups, similar to its predecessors like 'inclining images,' can be open to legal issues related to copyright infringement, irrespective of nature (intentional or inadvertent) of the motive. The issues related to absence of any clear terms of use, or lack of comprehension of misinterpretation of license by an average pattern reader, are yet to be satisfactorily addressed.

Therefore, if the aim is to reach broad, diverse, and global readership, both the pattern producers and the pattern prosumers need to exercise caution towards adopting new, unproven, techniques and technologies in representations of patterns. In particular, as the boundaries between actor classes fade, quality assurance will need to become a *shared* responsibility. In absence of a supervising authority and relying solely on an honor system, this can be admittedly difficult.

DIRECTIONS FOR FUTURE RESEARCH

It is still early to predict the outcome of the Social Web phenomenon in general and its impact on patterns in particular. The work presented in this paper can be extended in a few different directions that are briefly discussed next.

Social Network Analysis of the Pattern Community

The diversity and visibility of participants in public appearances such as events (conferences, meetings, and workshops) in different countries, postings on blogs, mailing lists, and newsgroups, and so on, indicates that the pattern community is thriving. A social network analysis (SNA) of the pattern community, as it continues to grow and morph into a dedicated social network, would be useful.

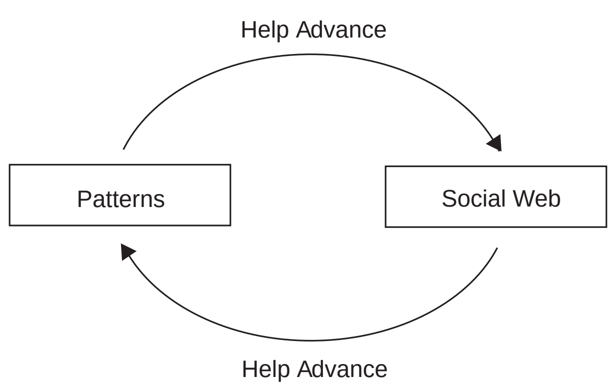
In particular, quantitative properties of the resulting graph such as centrality, closeness, clustering coefficient, cohesion, density, eigenvector centrality, and radiality, could be analyzed. This could help reveal certain relevant qualitative aspects of the network such as the relationships between actual actors; frequencies of use of specific patterns and pattern languages by certain actors; publications related to patterns and pattern languages recommended by people; demographical use of patterns; new domains of applicability of patterns; and so on.

Using Patterns for Social Web Applications

As shown in Figure 7, there is an apparent *symbiotic* relationship between patterns and the Social Web, one direction of which is explored by SW4PE in this paper.

The support for the other direction has been steadily increasing. The User Interface Design Patterns Library (http://ui-patterns.com/) provides, for instance, a TAG pattern and a TAG CLOUD pattern. There are patlets (Decker et al., 2006), patterns, and anti-patterns (Mader, 2008) available for making proper use of Wikis, which in turn could improve the collaboration between patterns authors and pattern readers. There are

Figure 7. The symbiotic relationship between patterns and the Social Web



design patterns for writing new microformats (Allsopp, 2007). There are also patterns available for computer-mediated communication in general (Schümmer & Lukosch, 2007) and for the design of Social Web applications in particular (O'Reilly, 2005) that can assist in the other direction. For example, APPLICATION SHARING, COLLABORATIVE SESSION, SHARED ANNOTATION, SHARED BROWSING, SHARED EDITING, and SHARED FILE REPOSITORY are patterns applicable to the Social Web context. It would be interesting to investigate the impact on the quality of collaboration and the quality of social (groupware) software that make use of these patterns. Finally, the design of Social Web applications typically corresponds to the PUBLISH-SUBSCRIBE architectural pattern.

The Convergence of the Social Web and the Semantic Web: Implications for Patterns

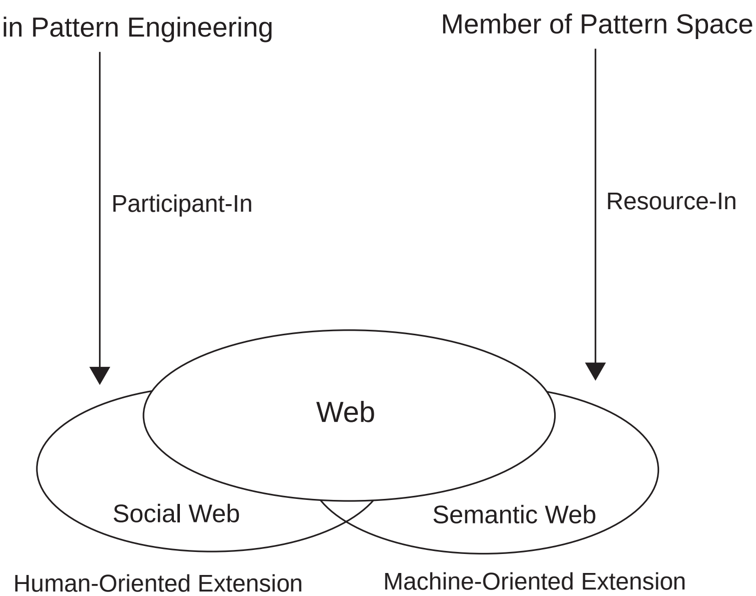
The Semantic Web has recently emerged as another perceived extension of the current Web that adds technological infrastructure for better knowledge representation, interpretation, and reasoning (Hendler, Lassila, & Berners-Lee, 2001). The Social Web efforts and the Semantic Web initiative are not competing but complementing, and need to co-exist. For the sustainability of the architecture of the Web, it is essential that the extensions of the Web evolve harmonically (Shadbolt, Hall, & Berners-Lee, 2006). For a unified view, the Social Web-specific efforts will need to take advantage of formalization (and thereby become more machine-oriented) and the Semantic Web-specific efforts will need to become more human-centric. This can be crucial for a future generation of PMS.

It would therefore be of interest to examine the synergies between the Semantic Web and the Social Web efforts, or as it is more commonly referred to by the pseudonym Web 3.0 (Lassila & Hendler, 2007), from the viewpoint of benefits and concerns to patterns. This, as the Figure 8 illustrates, is all the more significant since the actors in PE are participants in the Social Web and the members of the pattern space are resources in the Semantic Web.

Indeed, there are an increasing number of initiatives (Mika, 2007) that belong to the intersection of the Semantic Web and the Social Web, some of which may be relevant to PE. The Friend of a Friend (FOAF) and RELATIONSHIP are both Resource Description Framework (RDF) vocabularies: FOAF is used for expressing metadata about people, and their interests, relationships between them, the things they create, and activities they are involved in; RELATIONSHIP enriches FOAF by extending the types of relationships between people. As an example, the following is a combination of FOAF and RELATIONSHIP markup that represents the Myers-Briggs Type Indicator (MBTI) (Keirsey, 1998) of the shepherd John Smith and the relationship between John Smith and the author Steven Nash:

```
<?xml version="1.0" encoding="UTF-8"?>
<rdf:RDF
    xmlns:rdf="http://www.w3.org/1999/02/22-
     rdf-syntax-ns#"
  xmlns:foaf="http://xmlns.com/foaf/0.1/"
 xmlns:rel="http://purl.org/vocab/relation-
     ship/">
  <foaf:Person>
    <foaf:name>John Smith</foaf:name>
     <foaf:mbox rdf:resource="mailto:john.
     smith@john.smith.ca"/>
           <foaf:myersBriggs>ESTJ</
     foaf:myersBriggs>
    <foaf:knows>
      <foaf:Person>
        <foaf:name>Steven Nash</foaf:name>
      </foaf:Person>
    </foaf:knows>
    <rel:mentorOf>
      <foaf:Person>
        <foaf:name>Steven Nash</foaf:name>
```

Figure 8. The actors in PE and the members of the pattern space belong to the human and machine extensions of the Web, respectively



```
      </foaf:Person>
    </rel:mentorOf>
  </foaf:Person>
</rdf:RDF>
```

The limitations of these vocabularies are evident as they do not represent precise relationships among actors of patterns. For example, the `mentorOf` element is only an approximation to a shepherd.

The notion of an ontology perhaps forms one of the most important layers in the Semantic Web architecture. A formal representation of a pattern language as an ontology in the Web Ontology Language (OWL) enables better opportunities for organization and inferencing than that is possible by conventional means (Kamthan & Pai, 2006b). For example, an ontological representation of a pattern language allows making the implicit relationships between patterns explicit, which can complement [3] of PRP. However, the focus in this study is on technical rather than on social aspects. The aforementioned means of social collaboration could be useful towards ontology engineering of patterns, which is conducted in a social context (Gruber, 2004) and requires a considerate human effort to reach a consensus. These ontologies could be enriched by more knowledge about the actors. For example, the Semantically-Interlinked Online Communities (SIOC) Project aims to use Semantic Web technologies to connect people using different (Social) Web applications (like e-mail, blog or Wiki). The SIOC Core Ontology Specification explicitly uses RDF, OWL, and FOAF.

The other possibilities for a confluence between the patterns, the Semantic Web, and the Social Web from a research viewpoint are: a pattern language map in SVG could be generated from an OWL ontology and annotated with pattern reader-oriented tags to make it amenable to the tools for the Social Web; the FOAF – XFN and FOAF – hCard microformat connections from the perspective of an ontology of pattern language could be further exploited; the places where an ontology falls short could be compensated by the creation of a microformat for representation of patterns in

XHTML; the implications of Semantic Wikis on communication of patterns from an ontological viewpoint could be examined; and so on.

Patterns on the Mobile Social Web

It would perhaps not be an overstatement to suggest that in the last few years the ability to access the Web via a wireless device has been remarkably successful (Stanoevska-Slabeva, 2003). The potential of mobile access to the Social Web has evidently inspired the notion of Mobile Social Web, or more commonly known by the pseudonym Mobile Web 2.0 (Jaokar, 2006; Golding, 2008).

Due to the inherent constraints of both hardware and software (Tarasewich, 2003), it is unlikely that the Mobile Social Web could ever become 'de facto' environment for communicating the elements of PE. However, it could still serve as a means to facilitate collaboration in the PRP, in particular that of patlets, pattern thumbnails, and small pattern language maps, and for syndication. Further exploration of the interplay between patterns and the Mobile Social Web, particularly from the viewpoint of an extension to Figure 7, would be of interest.

Extending the Scope of SW4PE

The arguments presented in this paper accentuating the prospects versus highlighting the concerns of communicating the elements of PE via the Social Web are not exclusive. They could apply to other members of the pattern space as well as to other similar situations. For instance, as the number of anti-patterns grows, assessing the viability of the Social Web in communicating anti-patterns would be worth investigating.

The world of patterns is not secluded from other entities of knowledge. Indeed, software design patterns are related to (in the sense that they are influenced by or influence), for example, aspects, software engineering principles, Application Programming Interfaces (APIs), and software frameworks (Garzas & Piattini, 2005). The Social Web has potential benefits for these other entities of knowledge that are related to patterns and, in doing, so would benefit patterns indirectly. The same applies to the relationships between software patterns and other reusable software artifacts such as those identified in the Zachman Framework for Enterprise Architecture (Zachman, 1987).

There are various knowledge areas in the Guide to the Software Engineering Body of Knowledge (SWEBOK) and the Software Engineering Education Knowledge (SEEK) that require human-to-human communication. Further studies on topics, such as, integrating Social Web technologies/applications in requirements engineering (Macaulay, 1993), collaborative conceptual modeling, or in a socio-constructivist approach to software engineering education in general and in a collaborative approach to open source course projects in particular (Kamthan, 2007), would also be of research interest.

CONCLUSION

The creation and transfer of knowledge that occurs in PE rests strongly on human-to-human communication. This human-orientation needs to be acknowledged explicitly, and the Social Web provides an open and global environment for doing so.

The Social Web opens new vistas for the actors of patterns and indeed for the PRP itself. It celebrates a critical feasibility issue facing the pattern producers—that the number of pattern producers is less than the number of pattern consumers, and due to practical limitations on resources (in terms of time and effort) to dedicate, can not realistically be expected to explicitly document every possible view of patterns—a resolution to which results from the 'collective intelligence' of the pattern consumers. This, however, is not free of cost.

It is likely that by appropriate use of technologies/applications, some of the concerns outlined in this paper can at least be avoided if not entirely eliminated. It should, however, be noted that although certain limitations of the Social Web as it pertains to communication of patterns are transient, others are more fundamental.

The potential benefits of the Social Web can outweigh the costs in the long-term if the expectations are realistic and if an effort is made to address the associated concerns. If the past experience with the use of the Internet and the Web is any indicator, the movement has traditionally been towards flexibility, usability, and universality. The success between the interplay of patterns and the Social Web is likely to depend on these invariant values.

In conclusion, the shared benefits of any socialization for the purpose of communication of patterns can only come to fruition with the *shared* sense of accountability and responsibility on part of all actors. This can come only with coordination between pattern producers and pattern consumers. Therefore, an optimistic but cautious use of the Social Web is an imperative.

ACKNOWLEDGMENT

The author would like to thank the reviewers for their feedback and suggestions for improvement.

Section VIII
Emerging Trends

This section highlights research potential within the field of Web technologies while exploring uncharted areas of study for the advancement of the discipline. Chapters within this section highlight emerging semantic Web applications, Web personalization, and learning on the Web. These contributions, which conclude this exhaustive, multi-volume set, provide emerging trends and suggestions for future research within this rapidly expanding discipline.

ABSTRACT

This chapter introduces the general vision of the Social Semantic Desktop (SSD) and details it in the context of the NEPOMUK project. It outlines the typical SSD requirements and functionalities that were identified from real world scenarios. In addition, it provides the design of the standard SSD architecture together with the ontology pyramid developed to support it. Finally, the chapter gives an overview of some of the technical challenges that arise from the actual development process of the SSD.

DOI: 10.4018/978-1-60566-112-4.ch012

INTRODUCTION

A large share of everybody's daily activities centres around the handling of information in one way or the other. Looking for information, digesting it, writing down new ideas, and sharing the results with other people are key activities both in work as well as in manifold leisure activities. The abundance of PCs and the Web in today's world result in new numbers and qualities of information exchange and interaction which are seen both as chance and as threat by the users. Supporting personal and shared information handling is thus a highly requested but yet unsolved challenge.

In traditional desktop architectures, applications are isolated islands of data – each application has its own data, unaware of related and relevant data in other applications. Individual vendors may decide to allow their applications to interoperate, so that, e.g., the email client knows about the address book. However, today there is no consistent approach for allowing interoperation and a system-wide exchange of data between applications. In a similar way, the desktops of different users are also isolated islands – there is no standardized architecture for interoperation and data exchange between desktops. Users may exchange data by sending emails or uploading it to a server, but so far there is no way of seamless communication from an application used by one person on their desktop to an application used by another person on another desktop.

The problem on the desktop is similar to that on the Web – also there, we are faced with isolated islands of data and no generic way to integrate and communicate between various Web applications (i.e., Web Services). The vision of the SW offers solutions for both problems. RDF[a] is the common data format which builds bridges between the islands, and Semantic Web Service technology offers the means to integrate applications on the Web.

The Social Semantic Desktop (SSD) paradigm adopts the ideas of the SW paradigm for the desktop. Formal ontologies capture both a shared conceptualization of desktop data and personal mental models. RDF serves as a common data representation format. Web Services – applications on the Web – can describe their capabilities and interfaces in a standardized way and thus become Semantic Web Services. On the desktop, applications (or rather: their interfaces) will therefore be modelled in a similar fashion. Together, these technologies provide a means to build the semantic bridges necessary for data exchange and application integration. The Social Semantic Desktop will transform the conventional desktop into a seamless, networked working environment, by loosening the borders between individual applications and the physical workspace of different users.

By realizing the Social Semantic Desktop, we contribute to several facets of an effective personal information handling:

- We offer the individual user a systematic way to structure information elements within the personal desktop. Using standard technology to describe and store structures and relations, users may easily reflect and express whatever is important in their personal realm.
- Standardized interfaces enable the integration of all kinds of available desktop applications into the personal information network. Investments in programs, data collections, and hard-learned working styles are not lost but augmented and connected into a comprehensive information space.
- Based on the SW technology basis, all kinds of automated and semi-automatic support are possible, like, e.g., text classification services, image categorization, document relevance assessments, etc.
- The exchange of standard data formats between individual work spaces is supported not only on the technical level (e.g.,

standard communication protocols), but also on the semantic level (via sharing and alignment of ontologies and the corresponding annotated information elements). The integration with formal ontologies eases the sharing and understanding between different persons.

- Ultimately, we thus contribute to a solution for the initialization problem of the SW: As the individual user will receive immediate benefit from the semantic annotation within the personal workspace, the motivation is high to invest the necessary structuring and formalization work. As the standards used allow for an effortless sharing of such work, the amount of semantically annotated information which can be made available in the Web grows dramatically – which in turn makes it worthwhile to develop new SW-based services.

In this chapter we describe in detail the core components which are necessary for building a Social Semantic Desktop. We illustrate the necessary standard framework and describe the role and structure of the ontologies which support the spectrum from personal to social information handling. We outline the implementation decisions which need to be observed in order to realize a consequently ontology-oriented system, which is able to deal with the numerous flexibilities required within the Semantic Web. Finally, we show examples of the benefits obtained from the realization and use of an SSD.

The ideas and implementation principles presented in this chapter are distilled from our experiences in the NEPOMUK Project[b]. For each section we will describe the general motivation and principles and then give details on how the particular challenges have been solved in the NEPOMUK project.

BACKGROUND

The Social Semantic Desktop vision has been around for a long time: visionaries like Vannevar Bush (1945) and Doug Engelbart (1962) have formulated and partially realized these ideas. However, for the largest part their ideas remained a vision for far too long, since the necessary foundational technologies were not yet invented – figuratively speaking, these ideas were proposing jet planes when the rest of the world had just invented the parts to build a bicycle. Only in the recent years several technologies and research streams began to provide a foundation which will be combined and extended to realize the envisioned collaborative infrastructure of the SSD.

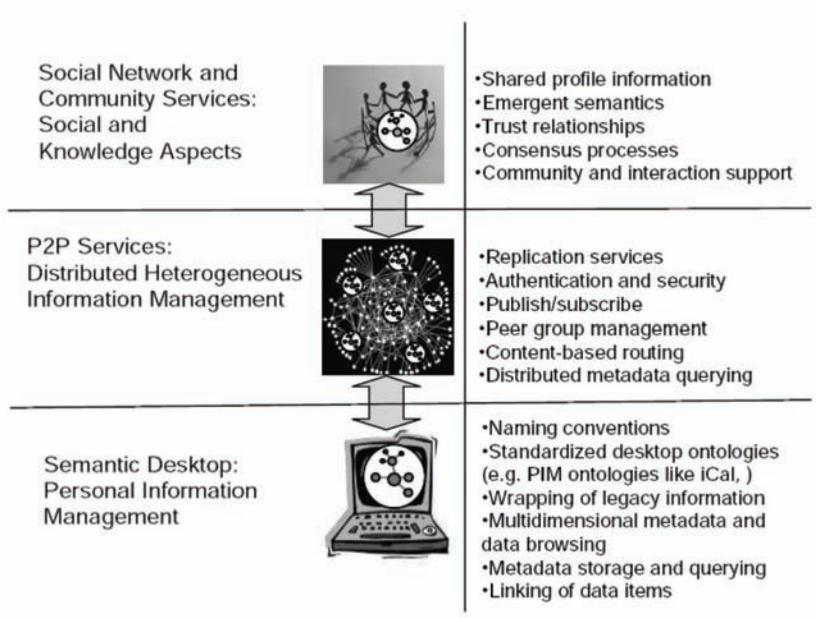
Figure 1 shows the highest-level architecture and connections between components of the SSD, i.e., the social networks, the P2P infrastructure, and the individual desktops. Traditional semantics, knowledge representation, and reasoning research are now interacting. While none of them can solve the problem alone, together they may have the explosive impact of the original Web:

The Semantic Web effort provides standards and technologies for the definition and exchange of metadata and ontologies. Available standard proposals provide ways to define the syntax (RDF) and semantics of metadata based on ontologies (Web Ontology Language – OWL (McGuiness et. al, 2004), RDF Schema – RDFS). Research covering data transfer, privacy, and security issues is now also under development.

Social Software maps the social connections between different people into the technical infrastructure. As an example, Online Social Networking makes the relationships between individuals explicit and allows the discovery of previously unknown relationships. The most recent Social Networking Sites also help form new virtual communities around topics of interest and provide means to change and evolve these communities.

P2P and Grid computing develops technol-

Figure 1. Component architecture of the Social Semantic desktop



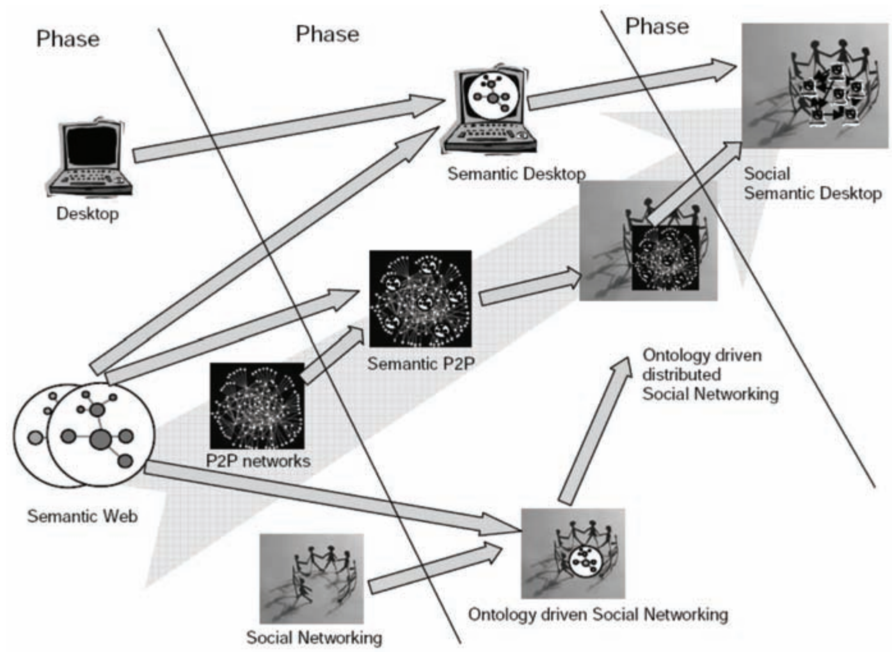
ogy to network large communities without centralized infrastructures for data and computation sharing. P2P networks have technical benefits in terms of scalability and fault tolerance, but a main advantage compared to central sites is a political one: they allow to build communities without centralized nodes of control, much as the Internet grew as fast as it did because it was based on reciprocity – it avoided political debate as to who gets to own big, expensive central facilities. Recent research has provided initial ways of querying, exchanging and replicating data in P2P networks in a scalable way.

By projecting the trajectory of current trends, we can simplify this picture by stating that next generation desktop applications will support collaboration and information exchange in a P2P network, connecting online decentralized social networks, and enabling shared metadata creation and evolution by a consensus process. The result of this process will be the Social Semantic Desktop. Figure 2 depicts the phases in which the relevant co-evolving technologies are combined to achieve the final goal, i.e., the realization of the Social Semantic Desktop.

SCENARIOS

Before we move on to the specific functionalities that a Social Semantic Desktop supports and discuss how they are implemented, we will first present some scenarios that will illustrate what an SSD is, how it will be used, and how it will change the way we do knowledge work. We chose the scenarios such that they illustrate the different dimensions of an SSD: Sect. *The Semantic Dimension* describes example usage that shows the use of semantics on the desktop, and Sect. *The Social Dimension* will show the social dimension of an SSD, i.e., the interaction between desktops of different users. The scenarios give an overview of what is possible and how the SSD presents itself to the user.

Figure 2. Phases towards the Social Semantic desktop



The Semantic Dimension

A typical use of a single Semantic Desktop is to organize ones data: files, emails, pictures, etc. Users are able to tag those information resources with concepts from a network of ontologies. The ontologies also contain relations (or properties, to use RDF terminology), which can be used to link information resources on the desktop. Organizing information resources in this way helps users to find what they are looking for quicker, and makes it possible for the Semantic Desktop itself to aid the user in their daily work. When a user first begins using the Semantic Desktop, many often-used concepts and properties are already present. E.g., there are basic concepts such as **Person**, **Meeting** or **Place**, and properties such as **knows** or **located-in**. Also, we can assume that useful things like an ontology of all countries are already in place. Then, as the need arises, users can extend the existing ontologies – e.g., they can add concepts for a particular meeting they attend or people they know, such as **Executive-Committee-Meeting-07/06/07**, **Jane-Doe** or **Hans-Schmidt**. The following two scenarios give examples of this kind of Semantic Desktop usage. We will use two imaginary users (*personas*[c]) flesh them out: Dirk, who works in a research group for some company in Germany, and Claudia, who is the group leader and his boss. Both Dirk and Claudia work on a project called Torque.

Organizing pictures (*Annotation*). Dirk just got back from his holidays in Norway, where he took a lot of pictures. Using his Semantic Desktop, he now wants to organize them, so that he can later find the pictures he wants to easier, generate photo albums for particular topics, etc. A lot of the important concepts probably already exist on his desktop, such as Norway, or the cities he has visited: **Oslo**, **Bergen** and **Trondheim**. Other concepts will be added by Dirk himself, such as **Holidays-in-Norway-2007** and tourist sights like **Preikestolen** or **Holmenkollen**. Since these concepts are more than just tags, Dirk can also say things *about* them, e.g., that **Holidays-in-Norway-2007** was a **Trip** and took place in **2007**, and that **Preikestolen** is a **Location** in **Norway**. Dirk even managed to take a picture of Prince Håkon and Princess Mette-Marit, so he creates two more concepts **Håkon** and **Mette-Marit**. There are many ways in which Dirk can link (or tag) his pictures to the relevant concepts – however, part of the Semantic Desktop are intuitive user interfaces, which hide most of the intricacies that go on under the hood from the user. E.g., Dirk might have an application that shows all the concepts that he is interested in the form of a tag cloud. Linking the pictures would then simply require him to drag them onto the desired concept in the cloud.

Planning a trip (*Context*). Later, Dirk finds out that he has to go on a work trip: a conference in Oslo. The Semantic Desktop assists him in planning and organizing this trip, through the notion of *context*. Dirk can create a new **Trip** object **Trip-to-OOC2007-Oslo** and tell his desktop that he is now in the context of this trip. This means that everything he does from this moment on will be interpreted as happening in that context, until he quits the context again. When he books a flight in his Web browser, the destination field will automatically be filled in with "Oslo", similarly the departure field. Afterwards, when he books a hotel room, he will be assisted similarly. Dirk will receive a number of email confirmations, such as the flight itinerary and booking confirmation for his hotel. These emails and their attachments will automatically be filed as belonging to the **Trip-to-OOC2007-Oslo** context, so that Dirk can easily find them again later. Once he knows his exact flight dates and where his hotel will be, he enters this information into his calendar, which is also context-aware and will therefore remember that these entries belong to Dirk's trip.

The Social Dimension

Users will have a lot of benefit from just using the Semantic Desktop on their own. However, by connecting to others, a number of additional possibilities arise.

Assigning tasks in a group (*Social Interaction*). In the previous scenario, Dirk found out he had to go on a business trip. In fact, he found out about this because he was notified by his boss Claudia, who also uses a Semantic Desktop. Claudia plans to travel to the OOC2007 conference in Oslo to present a research prototype her group has developed as part of the *Torque* project. She does not want to travel alone, so she first needs to find out who of her group members are available while the conference runs. Through the network of Social Semantic Desktops, her calendar application has access to the calendars (or parts of them) of all her contacts. She can ask the calendar to give her a list of all people in her group (**My-Research-Group**) who are working on the *Torque* project (**Torque-Project**) and are free when OOC2007 is on. She finds out that Dirk is free at the desired time. Just like Dirk in the previous scenario, she creates a **Trip-to-OOC2007-Oslo** object and makes it her current context. She also links the trip to the **Torque-Project**. Now, she creates a new **Task** object **Dirk-Prepare-Trip-To-OOC2007**, with a subtask **Dirk-Prepare-Presentation-Slides** and afterwards sends an email to Dirk, asking him to accompany her to the conference, book flights and hotel rooms, and prepare slides for the conference presentation. Her email and the task will of course be automatically linked to the proper context. Also, in this version of the scenario, Dirk no longer has to create the **Trip-to-OOC2007-Oslo** object himself – instead, it will be added to his Semantic Desktop automatically when he gets Claudia's mail.

FUNCTIONALITIES

In this section we describe a list of functionalities that are needed to support the scenarios mentioned above, as well as other scenarios developed during the NEPOMUK project. The SSD is a platform used to develop different kinds of social and semantic applications. These applications share

Table 1. Functionalities of the Social Semantic desktop

Desktop	Annotation, Offline Access, Desktop Sharing, Resource Management, Application Integration, Notification Management
Search	Search, Find Related Items
Social	Social Interaction, Resource Sharing, Access Rights Management, Publish/Subscribe, User Group Management
Profiling	Training, Tailor, Trust, Logging
Data Analysis	Reasoning, Keyword Extraction, Sorting and Grouping

common functionalities which must be supported by the SSD. We have divided them into five groups, which can be considered different aspects of the SSD. Tab. 1 shows the five different aspects and the individual functionalities within each group. Below we briefly describe the use of each functionality.

Desktop. At the *desktop* level, the semantic functionality common to most applications is the ability to add information about any resource. **Annotation** comprises the facilities to store and retrieve semantic relations about anything on the desktop. When Dirk annotates his photos from his trip, he does it from his most favorite photo application (such as Picasa or iPhoto), the annotations are then stored by the SSD. We name this functionality **Application Integration**; applications interact with the SSD by means of different services. When Dirk got notified about the trip to Oslo, this was an example of **Notification Management**. The SSD handles different kinds of mechanisms such as emails, RSS, or text messaging. When Dirk creates a new concept or even a new file on the SSD, the application he uses interacts with the **Resource Management** facilities of the SSD, creating the needed semantics according to the current context and setup. Some of the information Dirk needs when booking his trip are stored on Claudia's desktop. If she is not connected to the network, the **Offline Access** facility exports the relevant information to another desktop. **Desktop Sharing** is the ability for different users of the SSD to work on the same resources. Claudia might write a report of the trip together with Dirk: the resource management is done on Dirk's desktop, but Claudia can access and edit it remotely.

Search. The semantic network created on the desktop unleashes a whole new way of searching on the SSD. **Search** uses the semantic relations as well as social relations to retrieve relevant items. Once an item is found a user can also **Find Related Items**. For instance, when Dirk searches for a flight to Oslo, he can also search for related items and may find out that another company is actually cheaper, based on the experience of his social contacts.

Social. The SSD provides different means of **Social Interaction**, e.g., the embedding of semantic information in emails or text messaging, or the ability to annotate another user's resources. Some desktop level functionalities such as desktop sharing and offline access require the SSD to enable **Resource Sharing**. When Dirk and Claudia collaborate on the trip's report, Dirk might make it accessible to the whole group by adding it to a shared information space. When sharing resources or information on the network, the **Access Rights Management** of the SSD provides ways to define specific rights relations between users, groups and resources. The SSD's **User Group Management** system makes it easy for the rapid creation of new groups from a list of users. These groups can then be used to modify access rights or for resource sharing in a shared information space. E.g., some of Dirk's friends may have subscribed to get notifications of new pictures that Dirk annotates and makes available. The **Publish/Subscribe**

mechanism of the SSD facilitates the creation of feeds of relevant information.

Profiling. If enabled, the **Logging** functionality of SSD logs user activity, which may help to detect the current user's context. The *profiling* of the SSD can be done automatically by **Training**: the SSD learns to predict the user's behavior. The user can still **Tailor** the SSD's intelligent behaviors: some learned contexts can become irrelevant and may need to be re-adapted or removed. The notion of **Trust** on the SSD between people or information sources is also a result of the profiling of the desktop. Dirk might define that he trusts Claudia's information, or Claudia's SSD might learn that Dirk is a trustworthy source of information regarding the *Torque* project.

Data analysis. To support the training behaviors of the SSD or querying related items, the SSD provides different *data analysis* mechanisms such as **Reasoning**. For instance, when Dirk tags a picture with **Preikestolen** and **Norway**, the SSD may infer that Preikestolen is in Norway. This information can later be reused for search. **Sorting and Grouping** supports applications that perform search. The SSD returns items from many sources and people and sorts and groups these items regarding different criteria, using the semantics defined on these resources. The **Keyword Extraction** from resources such as text resources is useful for automatically tagging or summarizing.

ONTOLOGIES

Ontologies form a central pillar in Semantic Desktop systems, as they are used to model the environment and domain of the applications. The common definition of an ontology is "a formal, explicit specification of a shared conceptualization" (Gruber, 1995)

We distinguish four levels of ontologies for the SSD: *Representational*, *Upper-Level*, *Mid-Level and Domain*. The main motivation for having these layers is that ontologies at the foundational levels can be more stable, reducing the maintenance effort for systems committed to using them. A core principle of the Semantic Desktop is that ontologies are used for personal knowledge management. Each user is free to create new concepts or modify existing ones for his *Personal Information Model*. This modeling takes place on the domain-ontology level, but the user is of course free to copy concepts from the other layers and modify them to fit his or hers own needs. In order of decreasing generality and stability the four layers are:

Representation(al) Ontology. Representational ontologies (i.e., ontology definition languages) define the vocabulary with which the other ontologies are represented; examples are RDFS and OWL. The relationship of a representational ontology to the other ontologies is quite special: while upper-level ontologies generalize mid-level ontologies, which in turn generalize domain ontologies, all these ontologies can be understood as instances of the representational ontology. Concepts that might occur in the Representational Ontology level include: classes, properties, constraints, etc.

Upper-Level Ontology. "An upper ontology [...] is a high-level, domain-independent ontology, providing a framework by which disparate systems may utilize a common knowledge base and from which more domain-specific ontologies may be derived. The concepts expressed in such an ontology are intended to be basic and universal concepts to ensure generality and expressivity for a wide area of domains. An upper ontology is often characterized as representing common sense concepts, i.e., those that are basic for human understanding of the world. Thus, an upper ontology is limited to concepts that are meta, generic, abstract and philosophical. Standard upper ontologies are also sometimes referred to as foundational ontologies or universal ontologies." (Semy et. al, 2004) In the upper-level ontology you will find concepts like: **Person**, **Organization**, **Process**, **Event**,

Time, **Location**, **Collection**, etc.

Mid-Level Ontology. "A mid-level ontology serves as a bridge between abstract concepts defined in the upper ontology and low-level domain specific concepts specified in a domain ontology. While ontologies may be mapped to one another at any level, the mid-level and upper ontologies are intended to provide a mechanism to make this mapping of concepts across domains easier. Mid-level ontologies may provide more concrete representations of abstract concepts found in the upper ontology. These commonly used ontologies are sometimes referred to as utility ontologies." (Semy et. al, 2004). The mid-level ontologies may include concepts such as: **Company**, **Employer**, **Employee**, **Meeting**, etc.

Domain Ontology. "A domain ontology specifies concepts particular to a domain of interest and represents those concepts and their relationships from a domain specific perspective. While the same concept may exist in multiple domains, the representations may widely vary due to the differing domain contexts and assumptions. Domain ontologies may be composed by importing mid-level ontologies. They may also extend concepts defined in mid-level or upper ontologies. Reusing well established ontologies in the development of a domain ontology allows one to take advantage of the semantic richness of the relevant concepts and logic already built into the reused ontology. The intended use of upper ontologies is for key concepts expressed in a domain ontology to be derived from, or mapped to, concepts in an upper-level ontology. Mid-level ontologies may be used in the mapping as well. In this way ontologies may provide a web of meaning with semantic decomposition of concepts. Using common mid-level and upper ontologies is intended to ease the process of integrating or mapping domain ontologies." (Semy et. al, 2004). Domain ontologies consist of concepts like: **Group Leader**, **Software Engineer**, **Executive Committee Meeting**, **Business Trip**, **Conference**, etc.

Figure 3 shows how these four layers relate to the four ontologies created and used in the NEPOMUK Project. As detailed in Sect. "*Technology*", we were hesitant to make use of OWL for the representational ontology level in NEPOMUK, and in its place we developed the NEPOMUK Representational Language (Sintek et. al, 2007) (NRL). NRL defines an extension to the semantics offered by RDF and RDFS; the main contribution of NRL is the formalization of the semantics of named graphs. NRL allows multiple semantics (such as open and closed world) to coexist in the same application, by allowing each named graph to have separate semantics. The NEPOMUK Annotation Ontology (NAO) is a basic schema for describing annotations of resources, this is essentially a formalization of the tagging paradigm of Web2.0 applications. A specialized part of NAO is the NEPOMUK Graph Metadata schema (NGM) which allows the description of named graphs, defining meta-data properties such as the author, modification dates and version data.

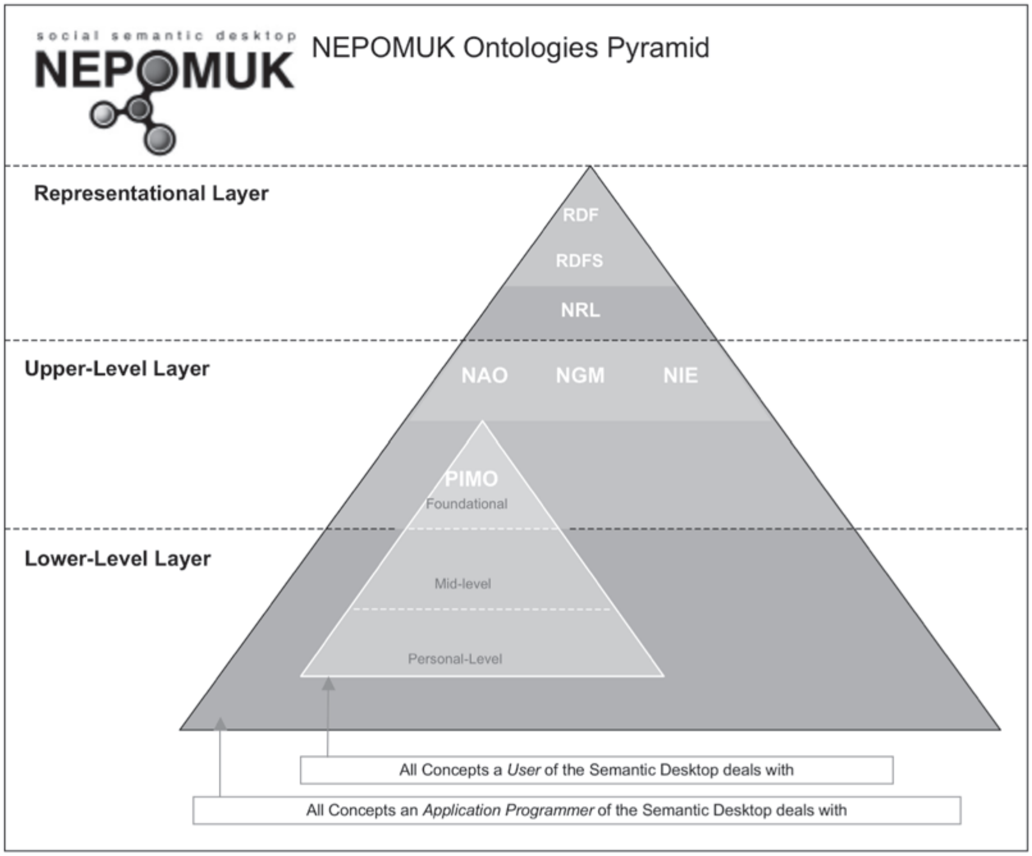
Finally, the NEPOMUK Information Elements ontology (NIE) contains classes and properties for describing objects found on the traditional desktop, such as files (Word documents, images, PDFs), address book entries, emails, etc. NIE is based on existing formats for file meta-data such as EXIF for image meta-data, MPEG7 for multimedia annotations, ID3 for music files, iCal, and others.

TECHNOLOGY

The Social Semantic Desktop deploys the Semantic Web on the desktop computer. Therefore, the technology stack proposed for the Semantic Web (the famous "Layercake"[d] adapted in Figure 4) is adopted for the SSD as well.

However, there are some specific considerations for the desktop scenario: everything on the desktop should identifiable by URIs. This is partially solved for files, where RFC1738[e] specifies the form of file:// URIs, but requires considerable

Figure 3. NEPOMUK ontology pyramid

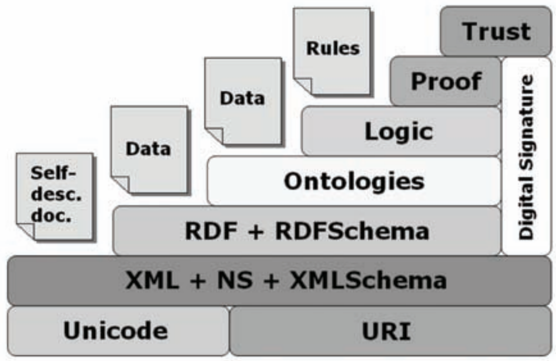


care for other applications which may not represent their data entities as individual files, such as address books or email clients.

Secondly, one can note that for the single desktop scenario there are fewer requirements on aspects such as trust, proof, and signatures. When one progresses to the Social Semantic Desktop, which involves interactions between many users, these aspects must be considered again.

In NEPOMUK we chose not to use the Web Ontology Language (OWL)(McGuiness et. al, 2004) as an ontology language, because of the challenge of dealing with (and implementing) OWL correctly; because our ontological modeling requirements were modest, and, most importantly, because OWL enforces an open-world view of the world, which did not seem to be appropriate for the (local) Semantic Desktop. In a World Wide Web context it is impossible for an application to read all available data, and an open-world assumption is natural, since additional data can be discovered at any moment. However, the open-world assumption makes it impossible to adopt negation as failure (Clark, 1978) which makes practical application development difficult and is also difficult to explain to the end-user. In the context of a local desktop application the situation is quite different, here it is perfectly possible to read all data available, and the closed world assumption makes much more sense. In place of OWL we developed our own ontology specification language called NRL, which uses the closed-world assumption. An additional RDF-based technology that we use widely, but which does not feature in the Semantic

Figure 4. The Semantic Web technology stack



Web stack is the concept of named graphs(Caroll et. al, 2005). This allows one to divide a larger RDF store into sets of RDF statements (graphs), where each is identified with a URI (the name). In this way it is possible to make meta-statements about each graph, such as provenance information. Named graphs thus become an alternative to RDF reification, which also allows making statements about other statements, but is harder to implement and creates a significant overhead. NRL does also allows applying different semantics for different named graphs, thus allowing us to integrate the local closed-world with the open-world of the extended Semantic Web.

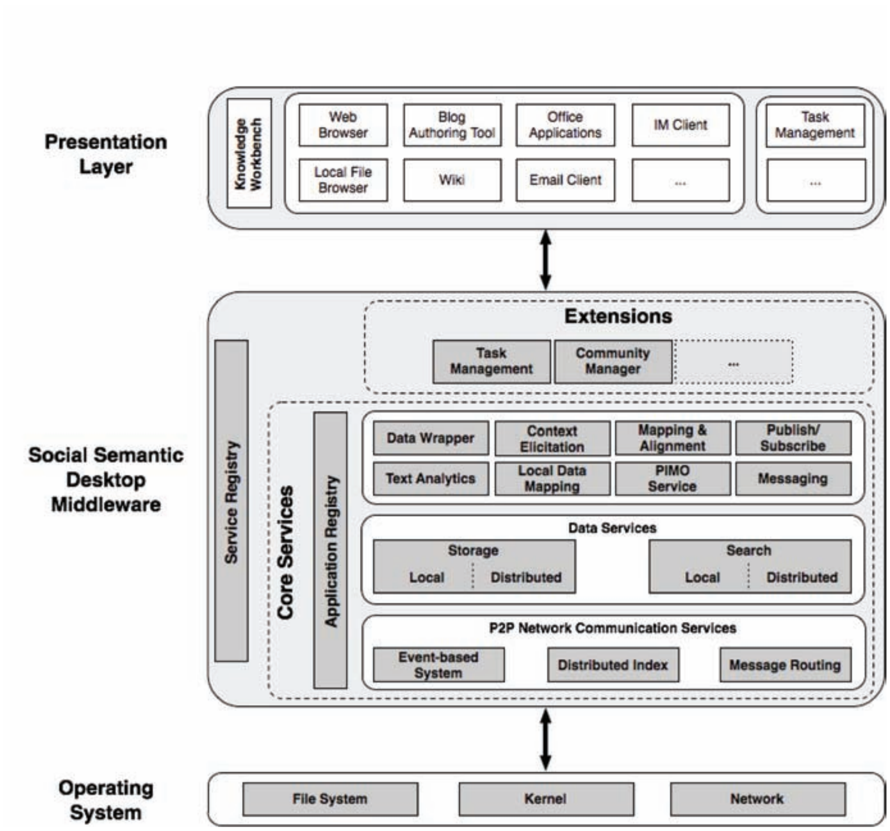
As noted previously, applications on the Semantic Desktop are analogous to services available on the Web. Each application will offer an interface for exposing the functionality it offers. Although a single desktop is not distributed, a network of SSDs is. It therefore suggests itself to adopt the Web Service stack of tools for inter-service communication for the Semantic Desktop: the Web Service Description Language (WSDL) [f] which is used for describing the interfaces of services offered, XML Schema (XSD)[g] which is used for primitive type definitions, and finally the Simple Object Access Protocol (SOAP)[h] which is used for the invocation of services. In Sect. "*Implementation and Engineering Principles*" we give further details on how these technologies work in relation to the Semantic Web technologies presented above.

ARCHITECTURE

In our vision, the standard architecture comprises a small set of standard interfaces which allow application developers to easily extend it and ultimately lead to an evolving ecosystem. Figure 5 depicts this set of interfaces transposed into services, together with their placement in the NEPOMUK architecture. The architecture has to reflect the two aspects of the scenarios introduced in Sect. "*Scenarios*", i.e., the semantic (which can operate on a single desktop) and the social aspect (which is relevant in a network of desktops). To cover these requirements and the functionalities discussed in Sect. "*Functionalities*", the SSD is organized as a Service Oriented Architecture (SOA). Each service has a well defined WSDL interface and is registered at the *Service Registry*. The social aspect of sharing resources over the network is enabled by the peer-to-peer (P2P) infrastructure of the architecture. In the following we present the services of the SSD.

The architecture, as show in Figure 5, is organized in three layers. Like current desktop systems, the desktop environment builds on top of the *Operating System* core, such as the file

Figure 5. Layered architecture of the Social Semantic desktop



system, kernel, and network environment. On the SSD the desktop environment is pooled in the *Social Semantic Desktop Middleware* Layer (SSD Middleware). The SSD Middleware groups the services of the SSD to be used in the Presentation Layer, which provides the user with SSD enabled applications that take advantages of the functionalities of the SSD.

The SSD is made up by individual desktops, which are organized in a P2P fashion. To support the communication between the peers, the SSD Middleware provides *P2P Network communication Services*. To enable information sharing between individual desktops, the RDF metadata of shared resources is stored in the *distributed index* of the P2P system. In NEPOMUK, the P2P system is based on GridVine (Aberer et. al, 2004), which in turn is built on top of P-Grid (Aberer et. al, 2003) and provides a distributed index with RDQL query supports.

Network Communication Services provide an *Event-based System*, which is responsible for the distribution of the events between the SSD peers. On the SSD, the event-based system is used to support the publish/subscribe system. Users as well as other services can use RDF to describe the kind of information they are interested in (e.g., new pictures of Norway become available, the status of a document changes to final, etc.). These subscriptions are stored in the distributed index of the P2P system. An event that was fired carries an RDF query as payload, which is matched against all subscriptions and triggers the notification of the subscriber. In addition, the *Messaging Routing* system uses RDF information to route messages to receiver.

The *Data Services* are responsible to control the insertion, modification, deletion, and retrieval of resources on the SSD. A resource can be a user, a document, a calendar entry, an email, and so on. It provides a service to store the RDF meta-data in the *Local Storage*. Resources and their RDF descriptions can either be added to the SSD manually, or the *Data Wrapper* or *Text Analysis* service extracts the information from desktop applications such as email clients or calendars. Data Wrappers are used to extract metadata form structured data sources (e.g., email headers, calendar entries, etc.). In NEPOMUK, data wrappers are implemented based on Aperture (Aperture, 2007). The Text Analysis service is used to extract metadata from unformatted text (e.g., email bodies, word processing documents, etc.). For local queries and for offline working the RDF metadata is stored in the *Local Storage*. If a resource is shared with other users in an information space, the meta-data is also uploaded to the distributed index of the peer-to-peer file sharing system. The *Search* service can either issue a *local* search in the local storage or a *distributed* search in the underlying P2P system.

Before new metadata can be added to the repository, we have to check whether this metadata describes resources that are already instantiated (i.e., an URI has been assigned) in the RDF repository. In this case, the URI of the resource should be reused, rather then creating a new one. This process is known as information integration (Bergamaschi et. al, 2001). The *Local Data Mapper* service takes over this responsibility in the SSD Middleware. E.g., the Data Wrapping service extracts contact information from the address book and stores the metadata in the repository. Since this is the first time information about the contacts is added to the RDF repository, a new URI is generated for each person. If later the Data Wrapping service extracts information from an email header, the Local Data Mapping service is responsible to lookup whether information about the sender of the email is already in the repository and reuse the corresponding URI instead of creating a new one (Sauermann et. al, 2006).

Ideally only one ontology exists for a domain of interest such as contact data, calendar events. In reality, however, we are faced with many ontologies of (partly) overlapping domains (e.g., FOAF and vCard for contact data, or different personal information models). Since individual users share information over the SSD, it is likely to happen that they use different ontologies for their annotations even when talking about similar domains. Therefore, the SSD Middleware provides a *Mapping & Alignment* service that can be used by other middleware services and services in higher layers to translate RDF graphs from a source ontology to a target ontology.

The SSD Middleware logs the actions a user performs on the resources on his desktop. The logged data is stored in the Local Storage and analyzed by the *Context Elicitation* service to capture the current working context of the user. The context can for example be used to adapt the user interface or to suggest meaningful annotations to the users, depending on the task they are currently working on.

As discussed in Sect. "*Technology*", the services on the SSD use RDF to exchange data. Therefore, services need the capability to generate and process RDF graphs. To simplify the handling of the RDF graphs, the *Ontology Service* provides an easy way to create and manipulate concepts in RDF graphs.

The *Publish/Subscribe System* allows users or other SSD services to subscribe to events on the SSD. The subscriptions are stored as RDF graphs in the distributed index. If an event occurs, the RDF query of the event is matched against the subscriptions. When the subscription, i.e., the RDF query, matches the event, the *Messaging* service looks up the preferred notification media (e.g., email, instant messaging, SMS) and delivers the messages. The Messaging System is further used for synchronous and asynchronous communication between SSD users.

The *Core Services* of the SSD Middleware comprise the services which provide the basic functionalities of the SSD. These services can be accessed via the SSD Application Programming Interface (API). If a developer wants to exploit the SSD Core Services to build his domain-specific application, he can do this as an *extension* of the SSD Middleware. An example for such an extension is the *Task Management* which provides functionalities such as creating, delegating, and manipulating of tasks. Finally, the *Application registry* allows applications from the Presentation Layer to register call back methods at the SSD Middleware if they need to be notified by SSD services, e.g., when a message arrives and has to be displayed to the user in an Instant Messaging Client.

The top layer of the architecture is the presentation layer. It provides a user interface to the services provided by the SSD, and is built using the SSD API. Many desktop applications are possible sources for resources that should be managed by the SSD. Therefore, each desktop application should integrate support for the SSD Middleware. Since this assumption does not hold for most of the current off-the-shelf applications, we developed plug-ins and add-ons to enable a seamless integration with existing applications. These plugins for example extract email or calendar data and add them as resources to the SSD. However, within NEPOMUK we also develop dedicated applications that make use of the SSD API directly, such as a semantic *Wiki* or *Blogging Tools*. (Möller et. al, 2006)

In addition, the *Knowledge Workbench* is the central place to browse, query, view, and edit resources and their metadata. In this way the Knowledge Workbench aims to replace current file management tools such as the MS File Explorer. If the SSD is extended by usage extensions, the application programmer also has to provide the corresponding user interface in the Presentation Layer (e.g., for Task Management, Community Management, etc.).

IMPLEMENTATION AND ENGINEERING PRINCIPLES

As detailed in Sect. "*Architecture*". we deem a Service Oriented Architecture (SOA) to be most suitable for the SSD framework. Furthermore, we decided to use the industry standard SOAP (Simple Object Access Protocol) for exchanging messages between our components. For traditional applications the names and structure of SOAP messages is specified using the Web Service Description Language (WSDL), which in turn uses XML schema data-types to specify the form of the objects being exchanged. However, since the formal modeling of the target domain using ontologies is the core idea of a Semantic Desktop application, the best-practices for SOAs are slightly different. In this section we will discuss some important differences from a traditional SOA system.[i] Basing a system architecture on underlying domain ontologies is similar in nature to Model Driven Architectures (MDA)[j]. However, on the SSD, ontologies take the place of UML models.

Working with RDF

Sect. "*Ontologies*" described the substantial effort that went into the modeling of our domains as ontologies in a formal language. These ontologies give us a very powerful and flexible modeling language, although the structure of instances of such ontologies at first sight seem much more constrained than complex XML schema data-types, the flexibility of RDF introduces some additional requirements for developers of components that should handle RDF instances:

- The structure of the RDF instances received may not be fully known at design time. This means one must take great care that the code does not break when encountering unknown properties in the data, and these unknown properties must also be preserved. In general, programming services for the Semantic Desktop is more like programming services for the web, rather than for traditional desktop applications, and one should follow the general rule of web-programming: "Be strict in what you send and tolerant in what you receive."

- Conversely, other services might not be aware of all the properties the local service uses. Therefore each service must be programmed to be tolerant of missing data and do their best with the data that was provided.

Passing Instances in Messages

Normally, when using SOAP in connection with WSDL and XML schema for data modeling, some mapping is used that will convert the XML schema definition to class definitions in the programming language of choice. Furthermore, stubs and skeletons will be generated for the service themselves, so that the details of communication are hidden. Programming against remote services is then indistinguishable from programming against a local object. However, when using services that pass instances for which the structure is defined by ontologies, the mapping is not so straight forward. Although interaction with RDF data can always be done on a completely general level using basic RDF APIs we are interested in facilitating the job of programmers consuming our services, and allowing them to work on a higher level than RDF triples. We identify three alternatives for programming web services where parameters are instances from an ontology:

- Starting with the ontologies, a number of tools[k] can be used to create a set of Java classes from the ontologies. The service interface is written using parameters of these types, and another tool is used to generate the WSDL and associated XML schema types from these. By sharing the URIs of the concepts in the ontologies with the URIs of the XML schema types, the semantics of messages is retained. The benefit of this approach is that much of the SOAP technology is retained, existing tools may be reused. Also, developers who are not familiar with Semantic Web technology will find that developing and using these services is unchanged from a normal Java environment. The main problem with this approach comes from the fact that ontologies are in general more dynamic than Java class definitions. In particular, as noted in Sect. "*Ontologies*", we expect the personal information models to change frequently. This approach requires a complete re-run of the whole tool chain and a recompile of the system when an ontology changes, as well as introducing some constraints on the ontologies.
- On the other end of the spectrum it is possible to bypass the parameter passing of SOAP all together, and rely more on the Semantic Web technology. Each method offered by a service will take a single RDF document (possibly including several named-graphs), and all the details about the message are given in these RDF graphs. An additional ontology for messages and parameters must be constructed, and some named-graph aware serialization (e.g., TriG or TriX[l]) of RDF is used to construct the XML SOAP messages. This approach was, for instance, used in the SmartWeb project[m]. The benefit of this approach is that the effort that has gone into modeling the ontologies is not duplicated for modeling objects. Also, the full expressivity of RDF may be used when modeling, as it not required that the instances fit into another representation. The backside to this flexibility is that it is significantly harder to program with RDF graphs than with simple Java objects, and both service developers and consumers need good

knowledge about RDF. One can of course envisage new tools that facilitate programming with such RDF messages, but since all the interesting details are hidden inside the RDF parameter, existing SOAP tools for development or debugging are no longer very useful.
- Finally, a hybrid approach of the two methods is possible. Here each method will retain multiple arguments, but each argument is represented by an RDF resource. We envisage two possibilities for doing this: either each parameter is given as a (*named-graph-uri*, *uri*) tuple pointing into an RDF document given as a special parameter; or, alternatively, each parameter is in itself an RDF graph plus the URI of the actual parameter (each RDF graph may contain several resources). The benefit of this method is that the changes in the ontology do no longer require a recompile of the system, while at the same time allowing slightly more compatibility with existing SOAP tools. The problem with this method remains that both client and server programmers need in-depth knowledge of RDF and the ontologies used.

Regardless of which of the three alternatives one chooses, it remains an important issue to make sure that the formal description of the services (i.e., the WSDL+XML Schema definitions) remain semantically correct and retain the pointers to the ontology concepts which the parameters represent. As mentioned, for the first approach this can be handled by well chosen URIs for the XMLSchema types. For the second and third approach the parameters have the form of simple string objects in both the WSDL definition and the SOAP messages, since the RDF serialization is represented as a string. However, both versions of WSDL available at the time of writing allow extensions to the WSDL format itself[n], and additional constraints on the type or form of the RDF instances contained inside the string parameters may be specified here. This is the approach taken by the *Semantic Annotation for WSDL and XML Schema* (SAWSDL) working group[o] and the NEPOMUK project makes use of their standard.

In this section we have considered a very lightweight approach to semantically enriching SOAP Web Services by passing RDF-based parameters. If a more powerful approach is required, the reader is advised to look into OWL-S[p] and the Web Service Modeling Language (WSML)[q], both defining much more sophisticated frameworks for Semantic Web Services.

RELATED WORK

In the following we review relevant research and development approaches for the Social Semantic Desktop. After providing a brief description, we discuss the lessons learned and state our conclusions.

Gnowsis (Sauermann, 2003) was among the first research projects targeting a Semantic Desktop system. Its goal is to complement established desktop applications and the desktop operating system with Semantic Web features, rather than replacing them. The primary focus of Gnowsis is on *Personal Information Management* (PIM). It also addresses the issues of identification and representation of desktop resources in a unified RDF graph. Gnowsis uses a Service Oriented Architecture (SOA), where each component defines a certain interface and it is available as an XML/RPC service.

The **Haystack** (Quan et. al, 2003) project presents a good example for an integrated approach to the SSD field. Inter-application barriers are avoided by simply replacing these applications with Haystack's own word processor, email client, image manipulation, instant messaging, etc. Haystack allows users to define their own arrangements and connections between views of information, thus making it easier to find information located in the personal space. The Haystack architecture can be split into two distinct parts: the Haystack Data Model (HDM) and the Haystack Service Model (HSM). The Data Model is the means by which the user's information space is represented, similar to what has been discussed in Sect. "*Ontologies*". The set of functionalities within Haystack is implemented by objects in the Haystack Service Model (HSM). Haystack has a standard three-tiered architecture, consisting of a user interface layer (the client), a server/service layer, and a database. Haystack was groundbreaking in terms of the dynamic creation of user interfaces, but the project ended before establishing any standards.

Another relevant personal information management tool is the **Semex System** (SEMantic EXplorer)(Dong et. al, 2005). Like other tools, it organizes data according to a domain ontology that offers a set of classes, objects and relationships. Semex leverages the Personal Information Management (PIM) environment to support on-the-fly integration of personal and public data. Information sources are related to the ontology through a set of mappings. Domain models can be shared with other users in order to increase the coverage of their information space. When users are faced with an information integration task, Semex aids them by trying to leverage data collected from previous tasks performed by the user or by others. Hence, the effort expended by one user later benefits others. Semex begins by extracting data from multiple sources and for these extractions it creates instances of classes in the domain model. It employs multiple modules for extracting associations, as well as allowing associations to be given by external sources or to be defined as views over other sets of associations. To combine all these associations seamlessly, Semex automatically reconciles multiple references to the same real-world object. The user browses and queries all this information through the domain model.

A similar idea is exploited by the **IRIS** Semantic Desktop(Cheyer et. al, 2005) ("Integrate. Relate. Infer. Share"), an application framework that enables users to create a "personal map" across their office-related information objects. IRIS offers integration services at three levels:

- Information resources (e.g., email messages, calendar appointments) and applications that create and manipulate them must be accessible to IRIS for instrumentation, automation, and query. IRIS offers a plug-in framework, in the style of the Eclipse architecture, where "applications" and "services" can be defined and integrated within IRIS. Apart from a very small, lightweight kernel, all functionality within IRIS is defined using a plug-in framework, including user interface, applications, back end persistence store, learning modules, harvesters, etc. Like Haystack, inter-application barriers do not exists, because all applications are made from scratch for IRIS.
- A Knowledge Base provides the unified data model, persistence store, and query mechanisms across the information resources and semantic relations among them. The IRIS user interface framework allows plug-in applications to embed their own interfaces within IRIS and to interoperate with global UI services, such as notification pane, menu toolbar management, query interfaces, the link manager, and suggestion pane.

DeepaMehta(Richter et. al, 2005) is an open source Semantic Desktop application based on the Topic Maps standard[r]. The DeepaMehta UI, which runs through a Web browser, renders Topic Maps as a graph, similar to concept maps. Information of any kind as well as relations between information items can be displayed and edited in the same space. The user is no longer confronted with files and programs. DeepaMehta has a layered, service oriented architecture. The main layer is the application layer, which offers various ways for the presentation layer to communicate with it via the communication layer (API, XML Topic Maps (XTM) export, EJB, SOAP). Finally, the storage layer holds all topics and their data either in a relational database or simply in the file system.

Other relevant projects include **Beagle++** (Brunkhorst et. al, 2005), a semantic search engine which provides the means for creating and retrieving relational metadata between information elements present on the destkop, **DBIN** (Tummarello et. al, 2006), which is similar to a file sharing client and connects directly to other peers, **PHLAT** (Cutrell et. al, 2006), a new interface for Windows, enabling users to easily specify queries and filters, attempting to integrate search and browse in one intuitive interface, or **MindRaider**[s], a Semantic Web outliner, trying to connect the tradition of outline editors with emerging SW technologies. The **MyLifeBits** project by Microsoft Research is a lifetime store of multimedia data. Though the system does not intent to be a SSD, one can learn from it how to integrate data, i.e., how to manage the huge amount of media and how to classify/retrieve the data(Gemmell et. al, 2002). It combines different approaches from HCI (Computer-Human Interaction) and information integration, while it lacks a conceptual layer beyond files. The **Apogée**[t] project deals with data integration in applications related to Enterprise Development Process (ECM). It aims at building a framework to create Enterprise Development Process-oriented desktop applications, independent from vendor or technologies. Finally, starting from the idea that everything has to do with everything, has a relationship with everything, **Fenfire**[u] is a Free Software project developing a computing environment in which you can express such relationships and benefit from them.

Although the systems we have looked at focus on isolated and complementary aspects, they clearly influenced the vision of the SSD presented here. Some of the architectural decisions made in the NEPOMUK project and presented in this chapter are similar to those of platforms like Haystack, IRIS, and DeepaMetha, e.g., in that we present a User Interface Layer, a Service and a Data Storage Layer. The modular architecture, also identified within the Haystack, SEMEX, and DeepaMetha systems, as well as the standardized APIs offer an easy way of introducing new components. Our approach guarantees that each component may be changed without affecting other components it interacts with. The interaction has to suffer only in the case in which the API of the component is modified. The NEPOMUK Architecture also provides service discovery functionalities: the NEPOMUK Registry providing a proper support for publishing and discovering the existing NEPOMUK Services by using a standard interface.

CONCLUSION

We presented the Social Semantic Desktop as a comprehensive approach to information handling. Oriented at the needs of knowledge workers, this approach centers around supporting the main information-oriented activities: The articulation of knowledge and the generation of new information items; the structuring, relating, and organization of information, and the sharing of formal and informal information within networks of co-operating people. From this, we derived key functionalities of the desktop, but also for search, social interaction, profile building, and data analysis.

Building the SSD relies on basic principles: Whatever appears within the personal workspace is treated as an information item. Content, relations, special services all refer to formal annotations of such information items, which in turn link between information items and personal information models. Unifying the flexibility and personal liberty of expressing whatever concepts seem relevant with the commitment to socially shared conceptualizations results in a layered hierarchy of ontologies which allow the necessary differences in stability, sharing scope, and formality. Integrating the tools of everyday information processing asks for an easy and flexible integration of existing desktop applications. Finally, the adoption of Semantic Web standard technology for representation and communication enables the easy transgression from personal annotated information to shared Semantic Web content.

Consequently, the architecture of the SSD combines standards-based data repositories with a rich middleware, which in particular allows for manifold service integrations and communications. On top of that, various presentation clients and specific applications support whatever activities are performed on the desktop. Such applications may be highly domain-specific, although core functionalities of knowledge work trigger standard applications, e.g., for document processing, task management, communication, etc.

The design decisions presented result in particular implementation and engineering principles; we outlined the adaptation to RDF, the service integration, and the message passing mechanisms in particular.

In summary, the SSD offers the basic technology and tools for everyday information processing by knowledge workers. In order to reach the intended wide acceptance and broad uptake, care was taken to make the central software components available under open source licenses, and to encourage the development and contribution of application-specific enhancements and adaptations. The concept of the SSD is promising and relies on a number of techniques which reach their maturity right now – consequently, a number of research and development projects are under way and contribute to the overall evolution of the concept.

Following the realizations described in this chapter, we see the SSD as a basis for the self-motivated generation of semantically annotated information, which will not only help the individual by allowing multitudes of specific services and support, but will also initiate a wide movement to populate the Semantic Web.

FUTURE RESEARCH DIRECTIONS

Although the ideas of the Social Semantic Desktop are based on solid foundations as presented here, the research areas surrounding this topic are still in their infancies. We will briefly discuss some of the pre-dominant challenges in the coming years:

Trust and Privacy. As pointed out in the Semantic Web technology stack presented earlier, a crucial component for any high-level Semantic Web service is the issue of trust and privacy. Trust touches on a wide range of issues, from the technical issues of cryptographic signatures and encryption, to the social issues of trust in groups and among individuals. These issues are all as valid for the Social Semantic Desktop as for the Semantic Web in general, or perhaps even more so, as people are less critical of putting personal data on their personal desktop.

User, group, and rights management. When a single personal Semantic Desktop allows easy sharing of information with the network of Social Semantic Desktops, determining access rights for this information becomes very important. The Social Semantic Desktop sets new requirements for distributed authentication, flexible group management, and fine-grained access rights, all the while remaining intuitive and unobtrusive for the end user.

Integration with the wider Semantic Web and Web 2.0. Currently we are talking about the Social Semantic Desktop as a network of Semantic Desktops built on the same standards. It is important to remember that the key benefit of Semantic technology is the easy access to integration with anyone using the same representational languages and ontologies. The growth of feature-rich Web applications is growing rapidly, and ensuring a strong bond between the Semantic Desktop and these services is a continuous challenge.

Ontologies and Intelligent Services. To date ontologies have been used to introduce a common vocabulary for knowledge exchange. On the Social Semantic Desktop ontologies are used to formalize and categorize personal information. This introduces many interesting issues around ontology versioning, ontology mapping, and ontology evolution. Furthermore, using ontologies with well-defined semantics will allow intelligent services to be built (e.g., using reasoning) that allow for much more than just browsing and (simple) searching.

User Evaluation. The underlying thesis of the whole (Social) Semantic Desktop effort is that the added semantics will improve productivity and enable new forms of cooperation and interaction which were not previously possible. In-depth empirical evaluation with real users of a Social Semantic Desktop systems are required to determine if this thesis really holds.

ADDITIONAL READINGS

Current and recent research and development in the SSD domain has already been presented in Sect. "*Related Work*". However, one influence that has not been covered in this chapter so far, but is closely related to the idea of a Semantic Desktop is the concept of *Semantic File Systems* – file systems in which files are not organized hierarchically, but rather according to their metadata. The concept and an early implementation are described in detail in (Gifford et. al, 2001).

Finally, as another entry point for additional reading, we would like to point the reader to the series of *Semantic Desktop Workshops* which were co-located with the International Semantic Web Conferences in 2005[v] and 2006[w].

From a historical perspective, the most important references in the Social Semantic Desktop domain are those by Vannevar Bush (1945) and Doug Engelbart (1962) which we mentioned in Sect. "*Background*". Another important early influence is certainly Ted Nelson's work on hypertext (Nelson, 1965). A modern vision of those ideas is a paper by Decker and Frank (2004), which also coined the term "Semantic Desktop". Of course, any work that is based on the ideas of the Semantic Web is not complete without references to seminal papers such as (Berners-Lee et. al, 2001) or (Hendler, 2001). In fact, the original vision of the World Wide Web itself already contained the idea of an information space that would reach from "mind to mind" (Berners-Lee, 1999); a thought that is central to the SSD.

Most of the references given in this chapter are of a technical nature. However, one has to keep in mind that the SSD is a tool for *information management* and *knowledge work*, and thus psychological and sociological research into the nature of knowledge work in any form are relevant as well. Oren (2006) provides a detailed overview of literature in this field, with the intention of applying the lessons learned to the development of the Semantic Desktop.

APPENDIX: QUESTIONS FOR DISCUSSION

Q: I prefer to handle my photo collection in a web 2.0 photo sharing environment. Is this compatible with the Social Semantic Desktop? May I keep the work I have invested here?

A: Yes. Every photo in your collection can be reached via a specific URI, thus it can be handled as a particular information item in the SSD. You might implement a suitable wrapper to transfer local annotations from your SSD onto the photo sharing platform, if you intend to disclose this information.

Q: The Social Semantic Desktop presupposes that everything is an information item. What about entities which are not information but real-world objects? Can I manage them in the SSD and add comments about them, e.g., about my friend's cat?

A: The solution is easy: Just create an appropriate description of the real world object within your SSD, thus creating an URI for the object in question. Let's say you create an instance of the class pet in your SSD (assuming you have this category within your SSD) and describe it as 'well-known house cat'. Then you can link this instance to, e.g., a photo of the animal, or you add an 'owns' link which connects it to the URI of your friend, and so on. Making an arbitrary object re-appear as a formal instance within the SSD models is often called 're-birthing', btw.

Q: Think about scenarios you encounter every day, and where the SSD can make your work easier.

A: The answer is of course a personal one, but for a typical knowledge worker (researchers, students, journalists, etc.) here are some example ideas:

- Show me related appointments when composing emails to a person, i.e., You also have lunch with Claudia next week.
- Show me previously viewed PDF documents on the same topic when researching on Wikipedia.
- Remember my meal and window preferences when booking flights.
- Remind me of my previous idea of combining topic A with topic B when reviewing my topic A notes.
- Let me connect an incoming email from a student to the colleague who introduced me to that student.

Q: What are the benefits of the Social Semantic Desktop compared to solution such as Microsoft Exchange server or the tight integration of applications on MacOSX? They also fulfil many of the functionalities required by the scenarios outline in this chapter.

A: The Social Semantic Desktop is different because of the standards used to build it. Firstly, by basing the representational layers of the Semantic Desktop on the existing (Semantic) Web standards we enable interoperability by a wide range of existing projects, and secondly, by creating new standards for desktop integration and data-formats we encourage future software developers to build on top of the Semantic Desktop. On the Semantic Desktop both the applications and the data encourages open access, and this exactly the opposite of the vendor lock-in that for instance Exchange Server aims for.

Q: Inspect the current state of the Semantic Web and the data available. What data-sources and/or ontologies do you think could be useful for integration with the Semantic Desktop?

A: The answer will of course change as the Semantic Web evolves, but at the time of writing relevant ontologies include:

- The Friend-of-a-Friend project – http://xmlns.com/foaf/spec
- The Description-of-a-Project schema – http://usefulinc.com/doap
- The Semantically Interlinked Online Communities project – http://siocproject.org/
- Dublin Core for basic meta-data – http://dublincore.org/
- Useful data-sources and/or web-services include:
- GeoNames for (reverse) geocoding – http://www.geonames.org/
- DBpedia for a Semantic Web view of Wikipedia – http://DBpedia.org/

ABSTRACT

In this chapter, we introduce the concept of explanation for Semantic Web applications by providing motivation, description, and examples. We describe the Inference Web explanation toolkit that provides support for a broad range of explanation tasks ranging from explaining deductive reasoning, to information extraction, to hybrid integrated learning systems. We argue that an explanation solution such as the one we endorse is required if we are to realize the full potential of hybrid, distributed, intelligent Web agents that users can trust and use.

INTRODUCTION

Question answering on the Semantic Web (SW) typically includes more processing steps than database retrieval. Question answering can be viewed as an interactive process between a user and one or more intelligent software agents. Using queries, user preferences, and context, intelligent agents may locate, select and invoke services and, if necessary, compose these services to produce requested results. In other words, the web paradigm shifts from one where users mainly retrieve explicitly stated stored information to a paradigm where application results are answers to potentially complex questions that may require inferential capabilities in addition to information retrieval. Web applications with question answering capabilities may still use information retrieval techniques to locate answers, but they may also need to use additional semantics such as encoded term meanings to support additional methods of information access (such as targeted database queries or knowledge base queries) along with information manipulations (such as reasoning using theorem provers, or inductive or deductive methods). Examples of this new, more complex reality include the automatic composition of web services encoded in OWL-S or semi-automatic composition of services as provided by workflows. Ontology-enhanced search is another example of how Semantic Web technology can provide and is providing new directions for a category of "smart" search applications. Many other SW applications are emerging with a common theme of increasing knowledge and autonomy. This new context generates an additional requirement for effective use of SW applications by typical users: *applications must provide explanation capabilities showing how results were obtained*. Explanations are quickly becoming an essential component in establishing agent credibility (e.g., Glass et al, 2008) and result credibility (e.g., Del Rio and Pinheiro da Silva, 2007) by providing process transparency, thereby increasing user understanding of how results are derived. Explanations can also identify information sources used during the conclusion derivation process. In the context of the SW, explanations should be encoded in a way that they can be directly or indirectly consumed by multiple agents, including both human users and software systems.

In this chapter we describe explanation as a special kind of pervasive SW functionality, in the sense that a SW application may need to provide transparency concerning its results. We first analyze some distinct application paradigms in the SW context, and for each paradigm we identify explanation requirements. We then describe a general framework, called Inference Web (IW) (McGuinness and Pinheiro da Silva, 2004) that includes the Proof Markup Language (PML) (McGuinness, et al., 2007, Pinheiro da Silva, McGuinness, Fikes, 2006), a modularized ontology describing terms used to represent provenance, justifications and trust relations. IW includes a set of tools and methods for manipulating PML-encoded result justifications. Using Inference Web, and its PML interlingua, applications may provide interoperable and portable explanations that support intelligent, interactive application interfaces. After the description of the IW framework and the PML interlingua, we will exemplify how PML and IW have been used to explain the results and behaviors of a wide range of applications including intelligent personal agents, information extraction agents, and integrated learning agents.

A CONCEPTUAL FRAMEWORK FOR EXPLAINING RESULTS FROM SEMANTIC WEB APPLICATIONS

We investigate the correspondence between SW application paradigms and their explanation requirements.

Semantic Web Application Characterization

SW applications are geared to take advantage of vast amounts of heterogeneous data with potentially varying amounts of semantic markup. They concentrate on identifying and meaningfully combining available semantic markup in order to derive complex results. Below we briefly characterize the SW applications features considered important from an explanation perspective: collaboration, autonomy, and use of ontologies.

Collaboration

Collaboration requires agents to interact and share knowledge with the common goal of solving a particular problem. Collaboration raises issues concerning how to create, use, and share a combination of provenance, trust and reputation throughout distributed reasoning processes. Wikis, for example, are gaining popularity as collaborative tools for human agents, although they do not provide a precise infrastructure for recording and reusing provenance information. A *Semantic Wiki* is a wiki application enhanced with Semantic Web technologies that support wiki content annotation that goes beyond simple structured text and untyped hyperlinks. Semantic Wikis provide the ability to represent metadata about content, term meanings, and inter-relationships. Provenance support is typically somewhat limited, in both ordinary wikis and in semantic wikis, to keeping track of which author (if a login authentication process is included) made which updates and when.

Content Management Systems (CMS) are one of the most common uses of wikis for knowledge management. Semantic Wikis aim to enhance ordinary wikis by allowing users to make their internal knowledge more explicit and formal, enabling search methods that go beyond simple keyword search. In this case, provenance information may be included in these searching capabilities. Other collaborative systems are aimed at Personal Information Management (PIM) or community knowledge management. The ability to store project history, and to utilize tools that access and perform intelligent queries over this history, is one of the benefits brought by Semantic Wikis used for content management.

The collaborative characteristic is also prominent in applications developed via the integration of multi-agent systems and Semantic Web services. In this situation, collaborating agents are software programs such as digital assistants that manage electronic information. These collaborating agents can proactively engage in tasks on behalf of their users to find, filter, assess and present information to the user in a more appropriate manner (Maes, 1994). Several types of multi-agent applications have been developed such as office organization (Pyandath & Tambe, 2002); technical support (Sullivan et al. 2000); and information retrieval (Rhodes et al., 1996). Again, most of these collaborating agents provide little support for storing and retrieving provenance information about how they work internally, and in particular, they provide only limited access to information about how they collaborate. However, end user activities may require the integration of multi-agent systems and Semantic Web services. Personal agents may also need user models, to allow them to better perform tasks in compliance with user needs and preferences.

Distributed solutions for multi-agent problems can alternatively be represented using a reactive multi-agent architecture. In these domains, the individual agents have little autonomy. The “intelligence” used to solve problems comes from intensive inter-agent communication. This paradigm is typically used on the web, where heterogeneity and loosely-coupled distributed systems are common. Thus, interactions between agents or system components must not be rigidly specified at design time, but opportunistically built though the use of new services as they become available. Prior knowledge of such services is thus not necessary (and often not practical nor desirable). Instead, agents must discover services by accessing a *service description* that can be semantically described by means of ontologies in which descriptive expressions or concepts are attached to services.

Autonomy

An individual agent’s autonomy controls its ability to act independently. Barber and Martin (1999) consider an agent’s degree of autonomy with respect to a particular goal that the agent is actively pursuing. Within this context, they define the degree of autonomy to be (1) the degree to which the decision making process was used to determine how that goal should be pursued; and

(2) how free the agent is from intervention by other agents. Traditional web-based applications have very little autonomy, since they primarily take direct input from the user and retrieve information consistent with the query. For example, a typical web search engine's primary interaction mechanism is based on communication between the user and the search engine. The degree of autonomy of the search engine is said to be low because the user is required to reformulate and resubmit the query when the original query is not satisfactorily answered by the engine. In contrast with typical search engines, SW applications have more autonomy while pursuing goals. For example, online shopping agents have autonomy over how to find answers to shopping queries concerned with product location, price comparison, or rating information. ShopBot can make several autonomous decisions, such as which content sources to use, which services to call and compose, and how to enhance the query with background representation information, all in an attempt to answer the user's question as efficiently and usefully as possible. In general, the development of autonomous problem-solving software agents in the Semantic Web is increasingly gaining popularity.

Use of Ontologies

Semantic Web applications are increasingly using large amounts of heterogeneous semantic data from multiple sources. Thus, the new generation of Semantic Web applications must be prepared to address issues associated with data of varying quality. Intelligence in these large-scale semantic systems comes largely from the system's ability to operate effectively with large amounts of disparate data.. In this context, ontologies are used to support information integration as well as to identify inconsistencies between data coming from multiple sources. Ontologies are being used to provide declarative specifications of term meanings. Agents can then decide to use a term meaning as specified in a particular ontology, and when multiple agents decide to use the same definition of a term (for example by referencing the same term in the same ontology), they can communicate more effectively. Usage of the same term, now with the same meaning, helps improve consistency across applications.

Content search and context search are other typical uses of ontologies. In content search, search engines use background knowledge bases to enhance queries and thus improve results. When the background knowledge bases contain term definitions, semantic query engines may be able to retrieve answers that are inferred by the query, no longer restricting the search to exact user-provided terms. Search engines can go beyond statistical clustering methods, which while effective, have limitations largely associated with training data sets. In context search, search engines may consider the user's context when processing a search. For example, a search engine may utilize a user's geographic location as well as known preferences when retrieving answers. Information about geographic location and preferences may be encoded in background ontologies.

Ontologies describing domain knowledge, user preferences, and problem areas are often used in creating agents with reasoning capabilities. These ontologies are often used to establish a common vocabulary among multiple agents. Personal agents' learning capabilities are also important, as such capabilities can increase the agents' level of autonomy (e.g., the Cognitive Assistant that Learns and Organizes (CALO, 2008). Personal agents can act alone or communicate with others in order to accomplish their task; in these cases, ontologies describing communications protocols are also necessary.

Explanation Issues

Given these Semantic Web application features which impact the need for explanation, we identify a set of criteria for analyzing the required explanations. These criteria include such issues as whether explanations are expected to be consumed by humans or machine agents; varying characteristics of these agents; and the resulting types of explanations that should be provided.

Explanation Types

System transparency allows users to see how answers are generated and how processes within and among agents have evolved to support answer generation. Transparency allows users to access lineage information that often appears hidden in the complex Semantic Web network. Note that explanations should be viewed as a web of interconnected objects recording source information, source assertions and assumptions, intermediate results, and final results instead of as a single "flat" annotation. Results from Semantic Web applications may be derived from a series of information manipulation steps, each of which applies a primitive information manipulation operation, e.g., an inference or extraction rule, on some antecedents and produces a conclusion. Note that an information manipulation step may be any kind of inference and is not limited to those that are used in sound and complete reasoners. Thus this representation can handle statistical methods, standard logical inference, or even non-logical information transformation methods. A justification may be viewed as a transaction log of information manipulation steps. When a user requests a detailed explanation of what has been done or what services have been called, it is important to be able to present an explanation based on this justification. These transaction logs may be quite detailed, so it is also important to be able to provide explanations that are abstractions of these logs.

Another kind of explanation can be obtained from provenance metadata that contains annotations concerning information sources, (e.g., when, from where, and by whom the data was obtained). Provenance metadata connects statements in a knowledge base to the statement sources such as web pages and publications, including annotations about data collection or extraction methods. Criticality of provenance is evident. Users demand detailed provenance metadata before they will accept and believe answers (e.g., Cowell, et al, 2006; Del Rio and Pinheiro da Silva, 2007). In some settings such where an initial evaluation of usefulness is made, provenance metadata (e.g., source, recency, and authoritativeness) is the only information that users need.

Trust in the Semantic Web is another subject of growing importance in the explanation context. Trust representation, computation, combination, presentation, and visualization present issues of increasing importance for Semantic Web applications, particularly in settings that include large decentralized communities such as online social networks (e.g., McGuinness, et. al, 2006).

Human or Machine Consumption

Semantic Web applications typically require explanation for both human and machine consumption. Software agents require representation of justifications, provenance and trust in a standard format in order to enable interoperability. An interoperable justification specification can be used to generate explanations of an agent's reasoning process as well as of the sources used by the agent during the problem solving process. Explanations aimed at either humans or software agents can be generated from the internal justification, provenance, and trust representations. When the explanations are aimed at humans, the explanations must also include human computer interface (HCI) considerations. For instance, the display of an explanation may take into consideration the level of expertise of the user, e.g., expert or non-expert, as well as the context of the problem (e.g., Del Rio and Pinheiro da Silva, 2007a). HCI researchers have approached the explanation problem by proposing intelligent question-answering systems (e.g., Maybury, 2003), intelligent help systems (e.g., Lieberman and Kumar, 2005), and adaptive interfaces (e.g., Wagner and Lieberman, 2003).

Visualization Capabilities

Explanations can be viewed as Semantic Web metadata representing how results were obtained. In distributed settings such as the Web, representation interoperability is paramount. A variety of "user friendly" rendering and delivery modes are required to present information to different types of users in varying contexts. As explanations may need to be delivered to users with a variety of skill levels, visual representation must be flexible, manageable, extensible, and interoperable. Additionally, corresponding presentation modes need to be customizable and context-dependent, and need to provide options for abstract summaries, detailed views, and interactive follow-up support. We consider several possible presentation modes. Implemented interfaces for each of these views can be seen in McGuinness, et al, 2006.

Global View. The entire process of explanation may be presented via a graphical display of a justification graph. The idea is to provide a view of the global structure of the reasoning process used by a question answering system. Common issues include how portions of information composing the explanation will be presented (for example, whether they are displayed in an English translation of the justification encoding, or in the reasoner's native language); or whether to restrict the depth and width of the explanation graph (e.g., with using notions such as lens magnitude and width options in the Inference Web browser). A useful feature in these kinds of views is to provide clickable hot links to enable access to additional information.

Focused View. Merely providing tools for browsing an execution trace is not adequate for most users. It is necessary to provide tools for visualizing the explanations at different levels of granularity and focus, for instance, to focus on one step of the justification, and to display that step using a natural language template style for presentation. Further focus on explanations can be provided by suggested context-appropriate follow up questions.

Filtered View. Alternative options may also be chosen, such as seeing only the assertions (ground facts) upon which a given result depended; only the sources used for ground assertions; or only the assumptions upon which the result depended. Another possible view is the collection of sources contributing information used to derive the result. Some users are willing to assume that the reasoning is correct, and as long as only reliable and recent knowledge sources are used, they are willing to believe the result. Initially, these users may not want to view all the details of the information manipulations (but they do want the option of asking follow-up questions when necessary).

Abstraction View. Machine-generated justifications are typically characterized by their complexity and richness of details that may not be relevant or interesting to most users. Filtering explanation information and providing only one type of information (for example, only showing the information sources) are some of the strategies used to deal with the large volume of data in justifications. These strategies translate the detailed explanation into a more abstract and understandable one.

In fact, this diversity of presentation styles is critical for broad acceptance of SW results. As we have interviewed users both in user studies (e.g., Cowell, et al, 2006; Del Rio and Pinheiro da Silva, 2007; Glass, et al., 2008) and in ad hoc requirements gathering, it was consistently true that broad user communities require focus on different types of explanation information and on different explanation formats. For any user segment that prefers a detailed trace-based view, there is another complementary and balancing user segment that requires an extensively filtered view. This finding results in the design and development of the trace-based browser, the explainer with inference step focus, multiple filtered follow-up views, and a discourse-style presentation component.

Explanation Issues vs. Semantic Web Application Characteristics

Having independently considered facets of both complex Semantic Web contexts and requirements for successful explanations, we now address how these issues relate to each other, providing requirements for explaining a broader range of SW applications.

Explanation and Collaboration

Trust and reputation are important issues in the context of collaborative applications and have been studied in the context of traditional wikis like Wikipedia (e.g., McGuinness, Zeng et al., 2006). The advent of semantic wikis introduces new concerns and requirements in terms of explanation. Autonomy among SW agents is continuously increasing, and if users are expected to believe answers from these applications, SW applications must support explanations. This requirement becomes even more important when SW applications collaborate to generate complex results.

As personal agents mature and assume more autonomous control of their users' activities, it becomes more critical that these agents can explain the way they solve problems on behalf of humans. The agents must be able to tell the user why they are performing actions, what they are doing, and they must be able to do so in a trustable manner. Justifications and task processing explanations are essential to allow personal agents to achieve their acceptance goals. In addition, the learning skill presented by some personal agents amplifies the need for explanation since it introduces a degree of variability resulting from learning results. Justifications concerning agent's internal reasoning for learning new knowledge as well as explanations concerning usage of knowledge sources are examples of what must be explained.

Distributed reasoning requires explanation capabilities to help users understanding the flow of information between the different agents involved in a problem solving process. These capabilities also allow users to understand the process taken by the distributed problem solvers. Additionally, provenance explanations are of interest since users might want to know information about each one of the learners and problem solvers used, as well as wanting to know information about each source of information that was used. Issues of trust and reputation are particularly likely to modify user's trust in agents' answers.

Explanation and Autonomy

In applications for which the degree of autonomy is low (for instance, a Google-based search query), no explicit explanation is provided. One could assume that aspects of explanatory material are implicitly embedded in the answers. In such settings, the user needs to have enough information to understand the context of the answers (e.g., the links selected by the query engine represent an information retrieval response to the query, and the answers include links to the sites containing the information). It is assumed that explaining why a search engine has selected a set of links is implicitly understood by the user (for instance, the search engine considers the provided answers to be the best responses, with some suitable definition of best which may rely on reverse citations, recency, etc.). The existence of a ranking mechanism is fundamental for the success of the interaction process because query reformulation depends on that ability. Understanding the process that led the search engine to provide an answer to a query facilitates the process of query refinement.

Even applications with low degrees of autonomy may experience demand from users for some forms of explanation. Users may want to know how a search engine got its answers, for example, if the answers were selected using certain purchased keywords or other advertising promotions, or if the answers depended on out-of-date source material. The information needs to be presented in an understandable manner, for instance, by displaying answers using purchased keywords in a different style.

Justifications become even more important in applications with higher degrees of autonomy. Autonomous agents can follow complex inference process, and justifications are an important tool for them to provide understandable information to end users.

Explanations and Ontologies

Ontologies can be used effectively to support explanations for a wide array of applications, ranging from relatively simple search applications to complex autonomous problem solving. For example, consider a contextual database search agent which considers user preferences when answering queries. Explanations of why a given solution was provided in a given context are particularly important when the solution does not match the user's specified preferences. Similarly, explanations are important when a particular contextual query results in different answers in different contexts (for example, when answers are dependent on the user's geographic location).

INFERENCE WEB: AN ONTOLOGY-ENHANCED INFRASTRUCTURE SUPPORTING EXPLANATIONS

We now explore Inference Web in the context of addressing the problem of providing explanations to justify the results and behaviors of Semantic Web services and applications. IW provides tools and infrastructure for building, maintaining, presenting, exchanging, combining, annotating, filtering, comparing, and rendering information manipulation traces, i.e., justifications. IW services are used by agents to publish justifications and explanations for their results that can be accessible digitally – on the web, on a local file system, or distributed across digital stores. Justification data and explanations derived from justifications are encoded using terms defined by the Proof Markup Language (PML) justification, provenance, and trust ontologies. The PML ontologies are specified in OWL and are easily integrated with Semantic Web applications. The ontologies include terms such as sources, inference rules, inference steps, and conclusions as explained later.

PML is an on-going, long-term effort with several goals and contributions to explaining Semantic Web application results and behaviors. Our earlier version of PML focused on explaining results generated by hybrid web-based reasoning systems, such as the question answering systems of DARPA's High Performance Knowledge Base program and its subsequent Rapid Knowledge Formation program. The requirements obtained for this initial explanation phase were similar to explanation requirements gathered for expert systems where knowledge bases were generated from reliable source information and using trained experts. Information in these systems was assumed to be reliable and recent. Thus, agent users only needed explanations about information manipulation steps, i.e. how the results were derived in a step by step manner from the original knowledge base via inference. In this setting, explanations concerning information sources used to derive results were not required.

As automated systems become more hybrid and include more diverse components, more information sources are used and thus users are seldom in a position to assume that all information is reliable and current. In addition to information manipulation, users may need explanations about information provenance. Under certain circumstances, such as intelligence settings that motivated DTO's Novel Intelligence for Massive Data program, provenance concerns often dwarfed all others when explanations were required (Cowell, et. al., 2006).

As automated systems begin to exploit more collaborative settings and input may come from many unknown authoring sources, notions of trust and reputation may become more critical. Meta information may be associated with authoring sources such as "I trust Joe's recommendations" or "I trust population data in the CIA World Factbook"). In these situations the meta-information may be user authored. In other settings, trust or reputation information may be calculated using techniques such as link analysis or revision analysis (Zeng, et.al. 2006).

Our goal is to go beyond explanation for traditional knowledge-based systems, and instead address explanation needs in a wide range of situations. We have settings where three different aspects of explanation sometimes dominate to the point that the other aspects are of secondary consideration. We thus took on a rationalization and redesign of our original representation Interlingua so that it could be modular. We can now support applications that only desire to focus on provenance (initially or permanently ignoring issues related to information manipulation and trust.). While these applications may later expand to include those concerns, they need not import ontologies with terms defined for those situations.

Using PML

To illustrate how PML supports explanation generation, we use a simple wine agent scenario. While this example is intentionally oversimplified, it does contain the question answering and explanation requirements in much more complicated examples. We have implemented a wine agent (Hsu, McGuinness, 2003) that suggests descriptions of wines to go with foods. The agent uses PML as its explanation interlingua, and a theorem prover capable of understanding and reasoning with OWL and outputting PML (Fikes, et. al., 2003)). The agent is capable of making wine recommendations to coordinate with meal courses (such as "Tony's specialty"). Before customers choose to follow the agent's recommendation, they may be interested in knowing a description of Tony's specialty, so that they can evaluate if the suggested wine pairing meets their desires. In this scenario, they would find that Tony's specialty is a shellfish dish and the wine agent suggests some white wines as potential matches. The user may want to know how the description of the matching wine was produced, and if the wine agent used other sources of information, such as commercial online wine web sites or hand built backend databases.

In some intelligence settings, e.g., (Cowell, et. al., 2006, Murdock, et. al., 2006), users often want to ask questions about what sources were relied on to obtain an answer. In some military settings, e.g., (Myers, et. al., 2007), users often want to ask what the system is doing, why it has not completed something, and what learned information was leveraged to obtain an answer. In other settings, such as collaborative social networks, users may be interested in either reputation as calculated by populations or trust as stated and stored by users, e.g., (McGuinness, et. al., 2006b). These setting are further elaborated in the following section.

Our PML explanation ontologies include primitive concepts and relations for representing knowledge provenance. Our original version of PML (Pinheiro da Silva et al., 2003) provided a single integrated ontology for use in representing information manipulation activities, the extended version of PML (called PML 2) improves the original version by modularizing the ontologies and refining and expanding the ontology vocabulary. This also broadens the reach covering a wider spectrum of applications for the intelligence, defense, and scientific communities. The modularization serves to separate descriptive metadata from the association metadata to reduce the cost of maintaining and using each module. The vocabulary expansion refines the definition and description structure of existing PML concepts; and it also adds several new primitive concepts to enrich expressiveness. For example, instead of simply serializing a piece of information into a text string, PML uses the concept of information as the universal reference to any piece of data, and enables explicit annotation (for instance, of format, language, and character encoding) about the string that serializes the piece of information.

PML provides vocabulary for three types of explanation metadata:

- The provenance ontology (also known as PML-P) focuses on annotating identified-things (and in particular, sources such as organization, person, agent, services) useful for providing lineage.
- The justification ontology (also known as PML-J) focuses on explaining dependencies among identified-things including how one identified-thing (e.g., information) is derived from other identified-things (e.g. information, services, agents).
- The trust relation ontology (also known as PML-T) focuses on representing and explaining belief assertions.

Provenance Ontology

The goal of the provenance ontology (also called PML-P[a]) is to annotate the provenance of information, e.g., which sources were used, who encoded the information, etc. The foundational concept in PML-P is *IdentifiedThing*. An instance of IdentifiedThing refers to an entity in the real world, and its properties annotate its metadata such as name, description, creation date-time, authors, and owner. PML-P includes two key subclasses of IdentifiedThing motivated by knowledge provenance representational concerns: *Information* and *Source*.

The concept Information supports references to information at various levels of granularity and structure. It can be used to encode, for example, a formula in logical languages or a natural language text string. PML-P users can simply use the value of information's *hasRawString* property to store and access the content of the referred information as a string. They may optionally annotate additional processing and presentation instructions using PML-P properties such as *hasLanguage*, *hasFormat*, *hasReferenceUsage* and *hasPrettyNameMappingList*. Besides providing representational primitives for use in encoding information content as a string, PML-P also includes primitives supporting access to externally referenced content via *hasUrl*, which links to an online document, or *hasInfoSourceUsage*, which records when, where and by whom the information was obtained. This concept allows users to assign an URI reference to information. The example below shows that the content of a piece of information (identified by #info1) is encoded in the Knowledge Interchange Format (KIF) language and is formatted as a text string. The second example below shows that the content of information (identified by #info_doc1) can be indirectly obtained from the specified URL, which also is written in KIF language.

```
<pmlp:Information
rdf:about=”#info1”>

<pmlp:hasRawString>(type Tonys-
Specialty SHELLFISH)

h</pmlp:hasRawString>
<pmlp:hasLanguage rdf:resource=
“http://inferenceweb.stanford.
edu/registry/LG/KIF.owl#KIF”
/>  <pmlp:hasFormat>text</
pmlp:hasFormat>  </
pmlp:Information>

<pmlp:Information
rdf:about=”#info_doc1”>

<pmlp:hasURL>http://iw.stanford.
edu/ksl/registry/storage/
documents/tonys_fact.kif/
pmlp:hasURL>   <pmlp:hasLanguage
rdf:resource= “http://infer-
```

```
enceweb.stanford.edu/regis-
try/LG/KIF.owl#KIF" />  </
pmlp:Information>
```

The concept source refers to an information container, and it is often used to refer to all the information from the container. A source could be a document, an agent, or a web page, and PML-P provides a simple but extensible taxonomy of sources. The Inference Web Registry (McGuinness and Pinheiro da Silva, 2003) provides a public repository for registered users to pre-register metadata about sources so as to better reuse such metadata. Our current approach, however, does not demand a centralized or virtual distributed registry; rather, it depends on a search component that finds online PML data and provides search service for users' inquiry.

```
<pmlp:Document rdf:about="#STE">

<pmlp:hasContent
rdf:resource="#info_doc1"/>

</pmlp:Document>
```

In particular, PML-P provides options for encoding finer grained references to a span of a text through its *DocumentFragmentByOffset* concept. This is a sub-class of Source and *DocumentFragment*. The example below shows how the offset information about #ST can be used to highlight the corresponding span of text (see Figure 1).

This type of encoding was used extensively in our applications that used text analytic components to generate structured text from unstructured input as explained below.

```
<pmlp:DocumentFragmentByOffset
rdf:about="#ST">

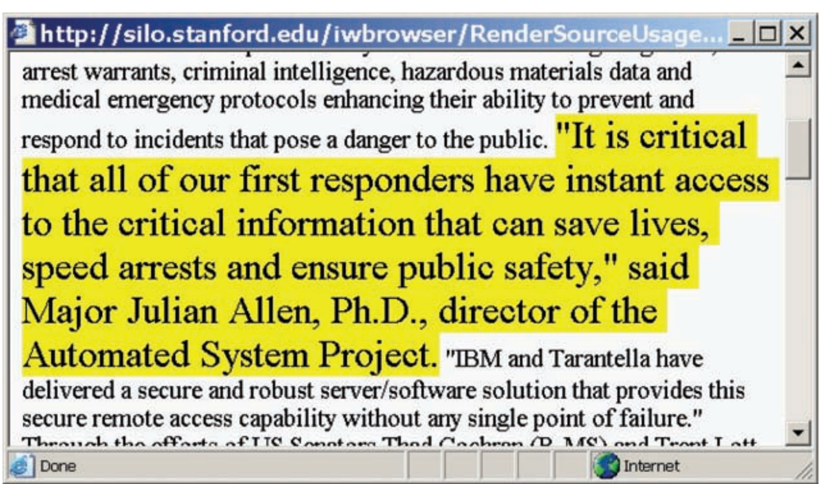
<pmlp:hasDocument
rdf:resource="#STE"/>

<pmlp:hasFromOffset>62</
pmlp:hasFromOffset>

<pmlp:hasToOffset>92</
pmlp:hasToOffset> </
pmlp:DocumentFragmentByOffset>
```

As our work evolved, a number of our applications demanded more focus on provenance. We became increasingly aware of the importance of capturing information about the dependency

Figure 1. Raw text fragment with highlighted segment used by text analytics components and represented in PML 2



between information and sources, i.e. when and how a piece of information was obtained from a source. PML 2 has a more sophisticated notion of *SourceUsage*. The encoding below simply shows how PML represents date information identifying when a source identified by #ST was used.

```
<pmlp:SourceUsage
rdf:about="#usage1">

<pmlp:hasUsageDateTime>2005-
10-17T10:30:00Z</
pmlp:hasUsageDateTime>

<pmlp:hasSource
rdf:resource="#ST"/>

</pmlp:SourceUsage>
```

Besides the above concepts, PML-P also defines concepts such as *Language*, *Inference-Rule*, and *PrettyNameMapping*, which are used to represent metadata for application processing or presentation instructions.

Justification Ontology

The goal of the justification ontology is to provide concepts and relations used to encode traces of process executions used to derive a conclusion. A justification requires concepts for representing conclusions, and information manipulation steps used to transform/derive conclusions from other conclusions, e.g., step antecedents.

A *NodeSet* includes structure for representing a conclusion and a set of alternative information manipulation steps also called *InferenceSteps*. Each InferenceStep associated with a NodeSet provides an alternative justification for the NodeSet's conclusion. The term NodeSet is chosen because it captures the notion that the NodeSet concept can be used to encode a set of nodes from one or many proof trees deriving the same conclusion. The URI of a NodeSet is its unique identifier, and every NodeSet has exactly one URI.

The term inference in InferenceStep refers to a generalized information manipulation step, so it could be a standard logical step of inference, an information extraction step, a simple computation process step, or an assertion of a fact or assumption. It could also be a complex process such as a web service or application functionality that may not necessarily be describable in terms of more atomic processes. InferenceStep properties include *hasInferenceEngine* (the agent who ran this step), *hasInferenceRule* (the operation taken in this step), *hasSourceUsage*, *hasAntecedentList* (the input of this step), and others.

PML2 supports encodings for several typical types of justifications for a conclusion. Three justification examples are as follows:

An unproved conclusion or goal. A NodeSet without any InferenceStep can be explained as an inference goal that still needs to be proved. Unproved conclusions happen when input information encoded in PML2 is provided to an agent.

```
<pmlj:NodeSet
rdf:about="#answer1">
<pmlp:hasConclusion
rdf:resource = "#info1" />  </
pmlp:hasConclusion>

</pmlj:NodeSet>
```

Assumption. The conclusion was directly asserted by an agent as an assumption. In this case, the conclusion is asserted by a source instead of being derived from antecedent information.

Direct assertion. The conclusion can be directly asserted by the inference engine. In this case, the conclusion is not derived from any antecedent information. Moreover, direct assertion allows agents to specify source usage. The following example shows that "'(type TonysSpecialty SHELLFISH)' has been directly asserted in Stanford's Tony's Specialty Example as a span of text between byte offset 62 and byte offset 92 as of 10:30 on 2005-10-17"

```

</pmlp:InferenceStep>

</pmlp:isConsequentOf>

</pmlj:NodeSet>
```

TOOLS FOR MANIPULATING EXPLANATION IN PML

To address the need to support multiple visualization modes for explanation, Inference Web provides rich presentation options for browsing justification traces, including a directed acyclic graph (DAG) view that shows the global justification structure, a collection of hyperlinked web pages that allows step-by-step navigation, a filtered view that displays only certain parts of the trace, an abstracted view, and a discourse view (in either list form or dialogue form) that answers follow-up questions.

Global View. Figure 2 depicts a screen shot from the IW browser in which the *Dag* proof style has been selected to show the global structure of the reasoning process. The sentence format can be displayed in (limited) English or in the reasoner's native language, and the depth and width of the tree can be restricted using the lens magnitude and lens width options, respectively. The user may ask for additional information by clicking hot links. The three small panes show the results of asking for follow-up information about an inference rule, an inference engine, and the variable bindings for a rule application.

Focused View. In Figure 3a, our explainer interface includes an option to focus on one step of the trace and display it using an English template style for presentation. The follow-up action pull down menu then helps the user to ask a number of context-dependent follow-up questions.

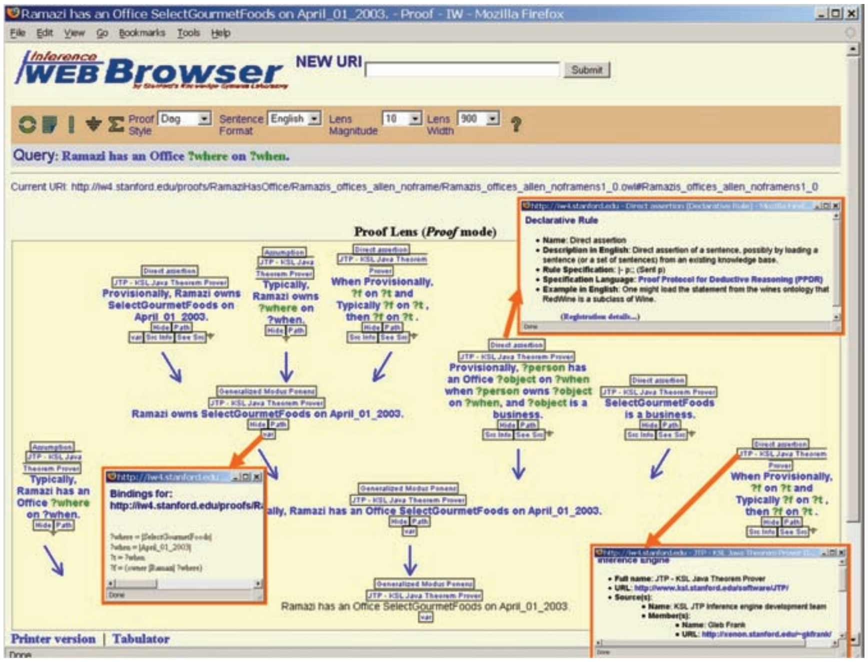
Filtered View. Figure 3b is the result of the user asking to see the sources.

Abstraction View. Inference Web approaches this issue with two strategies:

- Filter explanation information and only provide one type of information (such as what sources were used). This strategy just hides portions of the explanation and keeps the trace intact.
- Transform the explanation into another form. The IW abstractor component helps users to generate matching patterns to be used to rewrite proof segments producing an abstraction. Using these patterns, IW may provide an initial abstracted view of an explanation and then provide context appropriate follow-up question support.

The IW abstractor consists of an editor that allows users to define patterns that are to be matched against PML proofs. A matching pattern

Figure 2. Trace-oriented explanation with several follow-up question panes



is associated with a rewriting strategy so that when a pattern is matched, the abstractor may use the rewriting strategy to transform the proof (hopefully into something more understandable). An example of how a proof can be abstracted with the use of a generic abstraction pattern is shown in Figure 4. In this case, the reasoner used a number of steps to derive that crab was a subclass of seafood. This portion of the proof is displayed in the *Dag* style in the middle of Figure 4 (inside the blue round-angled box). The user may specify an abstraction rule to reduce the multi-step proof fragment into a one-step proof fragment (class-transitivity inference) on the left side of Figure 4.

We are building up abstraction patterns for domain independent use, e.g. class transitivity as well as for domain-dependent use. It is an ongoing line of research to consider how best to build up a library of abstraction patterns and how to apply them in an efficient manner.

Discourse View. For some types of information manipulation traces, particular aspects or portions of the trace are predictably more relevant to users than others. Additionally, the context and user model can often be used to select and combine these portions of the trace, along with suggestions of which aspects may be important for follow-up queries. Particularly for these types of traces, IW provides a *discourse view*, which selects trace portions and presents them in simple natural language sentences. In this interaction mode, the full details of the inference rules and node structure are kept hidden from the user. Individual nodes, provenance information, and metadata associated with those nodes, are used as input for various explanation strategies, which select just the information relevant to the user's request and provide context-sensitive templates for displaying that information in dialogue form. This same information is also used to generate suggested follow-up queries for the user, including requests for additional detail, clarifying questions about the explanation that has been provided, and questions essentially requesting that an alternate explanation strategy be used.

CASE STUDIES: PML IN ACTION

We will describe four applications that are using the IW framework and PML for explaining semantic information and behavior. We selected four applications that can be categorized differently following the conceptual framework.

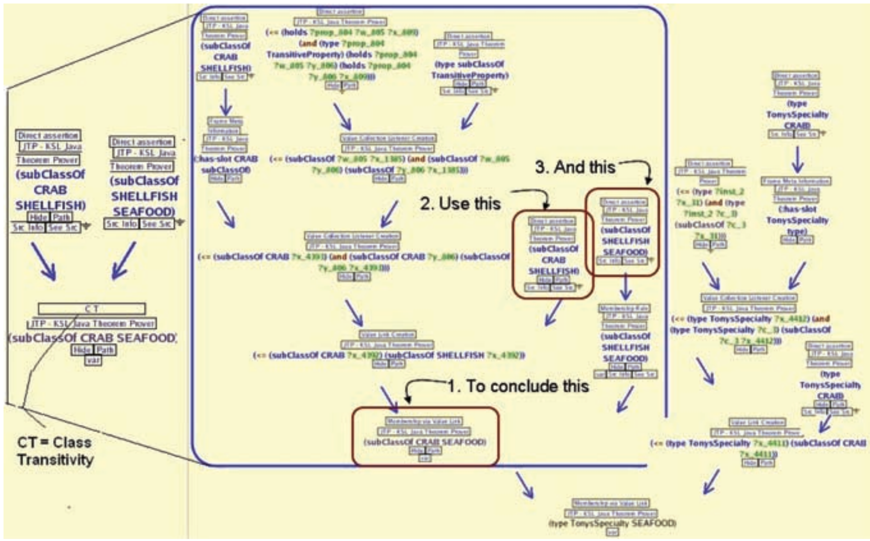
Cognitive Personal Assistants: CALO Example

IW and PML have been used by a DARPA-sponsored cognitive agent system called CALO that can be told what to do, reason with available knowledge, learn from experience, explain its recommendations, and respond robustly to surprise. The cognitive agent's actions are supported by justifications that are used to derive and present understandable explanations to end-users. These justifications reflect both how the actions support various user goals, and how the particular actions chosen by the agent were guided by the state of the world. More specifically, our approach to PML task justification breaks down the justification of a question about a particular task *T* into three complementary strategies, described here using terminology from SPARK (Morley & Myers 2004), the task engine used by CALO:

- **Relevance:** Demonstrate that fulfilling *T* will further one of the agent's high-level goals, which the user already knows about and accepts
- **Applicability:** Demonstrate that the conditions necessary to start *T* were met at the time *T* started (possibly including the conditions that led *T* to be preferred over alternative tasks)
- **Termination:** Demonstrate whether one or more of the conditions necessary to terminate *T* has not been met.

This three-strategy approach contrasts with previous approaches to explanation, most of which dealt with explaining inference (Scott et al. 1984, Wick & Thompson 1992). Previous approaches generally have not dealt with termination issues, and they also generally have not distinguished between relevance and applicability conditions. These are critical aspects of task processing and thus are important new issues for explanation.

Figure 4. Example of an abstraction of a piece of a proof



Behavior Justification in PML

In CALO context, PML documents contain encodings of *behavior justifications* using PML node sets. A task execution justification is always a justification of why an agent is executing a given task *T*. The final conclusion of the justification is a sentence in first order logic saying that *T* is currently being executed. There are three antecedents for this final conclusion, corresponding to the three strategies discussed above. Each antecedent is supported by a justification fragment based on additional introspective predicates.

It is important to note that all the task processing justifications share a common structure that is rich enough to encode provenance information needed to answer the explanation requests we have identified so far. By inspecting the execution state via introspective predicates, explanation components can gather enough provenance information to support a wide range of explanations.

Text Analytic Information Manipulations: KANI Example

KANI (Knowledge Associates for Novel Intelligence) (Welty, et. al., 2005, Murdock, et. al., 2006) is a DTO-sponsored intelligence analyst hybrid system that combines large scale information extraction with knowledge representation. In this section we focus on the relevance of provenance to support explanations of hybrid systems utilizing statistical and deductive inference.

In this setting, we can view all information manipulation steps in a PML justification as a kind of inference. We then generated a taxonomy of text analytic processes and tasks that can be viewed as inferences. The taxonomy was motivated by the need to describe and explain the dominant extraction tasks in UIMA[b], without overloading the system with more information than would be useful. One key was to generate a taxonomy that is adequate to accurately describe extraction task functionalities and simultaneously abstract enough to be able to hide details of the tasks from end users. Another key was to support explanations to end users of the integrated system, not authors of software components debugging their products.

We divided text extraction into three primitive areas: annotation, co-reference, and integration. We describe each briefly. Annotation tasks make assertions about spans of text that recognize a type or argument. Annotation inferences include:

1. **Entity recognition:** Determines that some span of text refers to an entity of a specified type. For example, a component could take the sentence "Tony Gradgrind is the owner of Tony's Foods" (the restaurant serving Tony's Specialty) and conclude that characters 0 to 14 of that sentence refer to some entity of type Person.
2. **Relation recognition:** Assigns a relation type to a span (e.g., a sentence describes a relation of type Owner).
3. **Relation annotation argument identification:** Determines and assigns values to the roles of a relation (e.g., a particular person is a participant in a given ownership relation instance).

Co-reference inferences utilize annotation inferences and further identify that multiple text spans actually refer to the same entity or relation.

1. **Entity identification:** Determines that a set of entity annotations refer to a particular instance.
2. **Relation identification:** Determines that a set of relation annotations refer to a particular relation instance.
3. **Extracted entity classification:** Determines that a particular co-referenced entity has a particular type. (e.g., the type of the entity referred to by "Gradgrind" is Person).
4. **Knowledge integration** inferences include mapping inferences providing access to provenance.
5. **Entity mapping:** Determines that an entity instance in the KB is derived from a set of entities and relation instances.
6. **Relation mapping:** Determines that a relationship in the target KB is derived from a set of entity and relation instances.
7. **Target entity classification:** Determines that an entity instance is an instance of an entity type in the target ontology.

We have registered these inferences in the IW registry and we use these information manipulation steps to explain all of the UIMA components used in our prototype system, which provides intelligence analyst support for analyzing documents and evaluating results of text statements.

Text Analytic Manipulation Descriptions

We use our taxonomy of text analytic manipulations in declarative descriptions encoding what was done to generate the extracted knowledge bases. UIMA generates a large extracted knowledge database containing its conclusions. We needed to take that as input (potentially augmented) and generate interoperable proof descriptions (a PML document) as an output.

The software component that produces PML documents for UIMA-based analysis processes begins with a specified result from a specified Extended Knowledge Database (EKDB) (e.g., TonyGradgrind is the Owner of TonysFoods). It follows the links in the EKDB from that conclusion back to the intermediate results and raw input that led to it. From these intermediate results, it is able to produce inference steps encoded in PML that refer to the corresponding tasks in the taxonomy. For example, if the EKDB records that characters 0 to 14 of some sentence were labeled as a Person and that this labeling was identified as specifying an occurrence of TonyGradgrind then the component would create an Entity Recognition inference step in PML for that labeling as well as coreference step for the result that the labeling is an occurrence of TonyGradgrind.

Transparent Accountable Data Mining: TAMI Example

TAMI (Weitzner, et. al., 2006) is an NSF-sponsored privacy-preserving system funded in the Cybertrust program. The idea is to provide transparency into the usage of data that has been collected, so that people may be able to see how data that has been collected about them has been used. In any accountable system, explanations are essential for providing transparency into the usage of information along with claims of compliance with privacy policies.

Usage policies are encoded concerning which organizations can use information for particular purposes. (The project specifically aims at usage instead of collection policies, so it is only use and reuse that is a topic for explanations). A transaction log is collected, which encodes data transfer information concerning transfers, policies, purposes, and organizations. Reasoning engines are used that evaluate the validity of transfer actions based on the encoded policies. These engines are instrumented to encode justifications for their determinations in PML, so that explanations can be provided about justified or unjustified transfers.

This system can be leveraged in a number of examples. One use case is in the explanation of justified or unjustified arrests. It is possible that data collected in compliance with rules for a particular purpose by an authorized agency may be reused to support a number of other conclusions. One prototype demonstration system in TAMI looks at arrests and then checks to see if they are justified according to their appropriate or inappropriate reuse of data that has been collected. Inference Web can then be used to explain why the system has determined that an arrest is legally justified or unjustified.

Integrated Learning Systems: GILA Example

GILA (Generalized Integrated Learning Architecture) is a DARPA-sponsored intelligent agent that integrates the results of multiple learners to provide intelligent assistant services. The initial domain is airspace control order deconfliction. GILA uses multiple independent learning components, a meta reasoning executive, and other components to make recommendations about ways to resolve conflicts in an existing airspace control order. In order to be operational, it must be able to explain its recommendations to end users and auditors. In addition, the explanations may be uses by learners and the meta executive to choose appropriate recommendations and assign credit and blame.

DISCUSSION

Explanation has been an active line of research since at least the days of expert systems, where explanation research largely focused on explaining rule-based systems. Today, explanation in rule systems is once again a research. Rule systems are now being integrated into hybrid settings, and now explanation must be done on both the rule components and the setting in which conclusions from those rule components are integrated and used. Also, theorem proving systems, such as Description Logic Reasoners, historically integrated explanation capabilities after usage increased and broadened. Early description logics that were broadly used, such as CLASSIC and LOOM provided some notion of explanation (e.g., McGuinness, 1996) in either insight into a trace or a proof theoretic-based approach to explanation. More recent explanation demands have inspired current generation tableaux-based DL reasoners to include some notion of explanation focusing on provenance, axiom usage, and clash detection (e.g., Parsia, et al, 2005, Plessers and Troyer, 2006). While all of these efforts are useful and important, today's explanation systems need to handle a much broader range of question answering styles and thus demand much more versatility and interoperability for their explanation infrastructure. Simultaneously, the infrastructure needs to be modular so that users with limited scope can support their applications without the burden of extra (unwanted) overhead. In our research on explaining provenance, we have recently modularized our explanation interlingua and the supporting background ontologies so that clients *only* interested in explaining provenance may use our infrastructure with the freedom of importing only the required modules.

Explanation requirements often arise in many settings that do not simply use standard deductive reasoning components. Our work, for example, has taken us into the realm of explaining text analytic components and a wide range of machine learning components. As a result, we have explored and are continuing to explore representation, manipulation, and presentation support for explaining systems that may use statistical, incomplete, and/or uncertain reasoning paradigms. Explanation research has also branched out into settings such as collaborative social networks, and we have engaged in research aimed particularly at explaining systems embedded in or leveraging large distributed communities. In many of the more recent research areas, we have found many requirements concerning trust, ranging from trust calculation to trust propagation, as well as presentation issues related to filtering by trust.

One relatively active area of provenance explanation is in the field of scientific applications. Increasingly, virtual collections of scientific data are being enabled by semantic technology (e.g., Virtual Observatories such as the Virtual Solar Terrestrial Observatory (McGuinness, et al, 2007). Such repositories are much more likely to be usable and to be used when provenance is maintained and available concerning where the data came from. More recently, there has been emphasis on additionally explaining the workflow from which it was produced. Thus, there is an emerging emphasis on explaining scientific provenance and workflow.

FUTURE RESEARCH DIRECTIONS

We have active research plans in a number of areas related to explanation.

1. **Learning.** Increasingly hybrid systems are depending on individual or multiple learning components to provide either ground facts or sometimes procedures. We are currently working multiple learning component authors to provide explanation components for learned information and learned procedures.
2. **Provenance.** The importance of provenance seems to be growing in many fields and we are focusing on providing relatively lightweight explanation solutions for provenance. We are also exploring special purpose needs of interdisciplinary scientific applications with respect to provenance.
3. **Trust.** Our current trust model is relatively simplistic and we are investigating ways of providing more representational primitives, methods for automatically suggesting trust ratings, and methods for intelligently combining and explaining combined trust values.
4. **Evaluation.** We have developed a PML validator that checks to see if an encoding is valid PML. We are extending that to provide an ontology evaluation module that not only checks for syntactic and semantic correct-

ness, but also reviews (and explains findings concerning) ontology modeling styles.

CONCLUSION

In this chapter, we have explored the growing field of explanation. We noted that as applications become more autonomous, complex, collaborative, and interconnected, the need for explanation expands. We presented a modular interlingua capable of representing explanations that focus on provenance, justifications, and trust. We also presented the Inference Web infrastructure for manipulating explanations in a wide range of application settings. We provided examples in a diverse set of domains showing different settings where explanations are required, and then described how Inference Web and PML are being used to meet these needs. We also presented a number of different presentation paradigms for explanations.

ACKNOWLEDGMENT

We have benefited greatly by working with a number of excellent collaborators including Bill Murdock, Chris Welty, and Dave Ferrucci from IBM and Andrew Cowell, Dave Thurman, and colleagues from Battelle on NIMD, Michael Wolverton, Karen Myers, David Morley from SRI on CALO, Danny Weitzner, Tim Berners-Lee, Lalana Kagal, Chris Hanson, Gerry Sussman, Hal Abelson, Dan Connolly, Sandro Hawke, Kay Waterman, and colleagues from MIT on TAMI, and a large contingent of collaborators on GILA including Ken Whitebread, Martin Hofmann, Phil DiBona, Steve Wilder from Lockheed Martin and collaborators in multiple universities on the project related to learners and meta reasoning. This work has been partially supported by contract numbers: 55-00680, PO TT0687676, 5710001895-2, 2003*H278000*000, HR0011-05-0019, and F30602-00-1-0579.

ABSTRACT

This chapter presents an architecture for the integration of various algorithms for digital image processing (DIP) into web-based information systems. The proposed environment provides the development of tools for intensive image processing and their integration into information systems by means of JAVA applets. The functionality of the system is shown through a set of tools for biomedical application. The main feature of this architecture is that it allows the application of various types of image processing, with different computational costs, through a web browser and in a transparent and user-friendly way.

DOI: 10.4018/978-1-60566-002-8.ch022

INTRODUCTION

The rapid advance of the medical imaging field is revolutionizing medicine. Technologies such as computed axial tomography (CT Scan), magnetic resonance imaging (MRI), Helicoidal CT Scan, and the fusion of CT Scan and positron emission tomography (PET), all provide an effective map of the human anatomy in a non-invasive manner.

Clinical practice usually relies on computing techniques to simplify the diagnosis of the medical expert. Medical imaging is not restricted to the visualization of anatomical structures, it is also used for diagnosis, surgical planning, simulation, radiotherapy planning, etc. These applications enable the clinicians to virtually interact with the anatomical structures and as such achieve the knowledge that enhances their performances. All the aforementioned techniques belong to a discipline known as Digital Image Processing (DIP). Traditionally, the medical DIP applications were carried out in expensive work-stations provided by the CT or PET machine supplier. These kinds of applications have certain drawbacks, such as administration and maintenance, which make them unsuitable for some environments.

The current trend in software development is the creation of applications that can be integrated into a Web environment and enjoy advantages such as placement independence, centralized application maintenance, and the use of firewalls without changing the filter rules. Web applications have proliferated due to their rapid learning and easy use as well as their personalization capability that provides a user-friendly interface. This trend towards Web developments is also being introduced into the medical field, to the detriment of the traditional clinical applications. DIP-related applications have high computational costs and therefore hospitals have to invest heavily in computing equipment in order to provide the clinicians with powerful mainframes. At this point, it seems logical to differentiate between algorithms of low and high computational cost.

It should be borne in mind that, as DIP is not a recent discipline, there exist libraries that include different algorithms for digital image processing. Already implemented algorithms should therefore be reused in new developments.

State of the Art

There currently exists a wide range of applications that allow the digital processing of medical images by means of a Web browser. The following list represents applications with two common factors: the DIP is processed at the client and the implemented algorithms tend to have a low computational cost.

- RAIM Java is a DICOM (Digital Imaging and Communication in Medicine) image viewer for biomedical imaging that was developed by the Biomedical Digital Imaging Center of UDIAT-CD S.A. (http://www.cspt.es/webcsptcastella/udiat/default.htm). This viewer was developed with Java technology and can therefore be used in almost any computer and graphic operative system. Since the visual display was conceived as an applet, it has to be executed within a Web browser; this allows the images to be processed in various ways, such as change of visualization window (Window-Level), rotation, scale, etc.
- CHILI: Digital radiology (http://www.chili-radiology.com) is a set of software components oriented towards tele-radiology and PACS (Picture Archiving and Communication Systems). It is a product from CHILI GmbH (Germany) and was developed in cooperation with the German Cancer Research Center and the *Steinbeis Transferzentrum Medizinische Informatik* company. CHILI WEB is one of its products and is composed by the CHILI/Web Server with the CHILI/Web Client. The CHILI/Web Server first receives the images of the modalities through the DICOM protocol and later stores them in a relational data base. The CHILI/WEB Server can work with an existing PACS. The CHILI/

Web Client is a platform-independent program developed with Java.

- RemotEye(http://eng.neologica.it/prodotti/remoteye) is a DICOM display developed by NeoLogica.it. which allows the visualization of DICOM imaging though Internet and offers the possibility of performing certain types of digital image processing such as geometrical transformations, changes of brightness and contrast, etc. It can easily be integrated with the PACS.
- MagicWeb/ACOM.Web (http://www.medical.siemens.com) was developed by Siemens and provides the publication of images and reports for an entire welfare centre with the aim of allowing clinicians to consult from different places. One of its characteristics is the optimization of imaging visualization, since images can be seen with different brightness and contrast levels, augmentation, compression, cinema mode, filters, etc.

On the other hand, there also exists a series of applications that use intensive processing for the performance of different algorithms and rely on complex computing developments, since they can not be executed within a Web browser. The following list represents various developments with complex computational DIP requirements.

- A good option for the development of distributed applications is the CORBA interface for communication among remote objects. This technology allows not only the integration of various languages on different machines but also a total interconnection among all the applications. An example of the use of this technology is the Image Processing Tool (http://imageprocess.sourceforge.net), a distributed processing system based on open-source software that uses a client-server architecture. The main shortage of this software is that, inherently to the use of CORBA, two machines cannot communicate through the Internet due to possible intermediate firewalls.
- The IRMA (image retrieval in medical applications) (http://phobos.imib.rwth-aachen.de/irma/index_en.php) is a distributed system developed by the Computing Department of the University of Aachen (Germany). This system provides not only uniform access to different modalities of medical imaging but also the application of different types of distributed processing algorithms to the images. The proposed architecture has a client-server structure and involves a central database, a task planner, and several processing daemons. The planner distributes the processing load among the different processing daemons installed at processing stations, which provides a low cost and high performance system. The main disadvantage of such a system is the communication between the client and the server on TCP-IP through non-standard protocols, and the non-multiplatform nature of the client.
- The Diamond Eye (Burl et al, 1999) architecture was developed by NASA laboratories and created initially to recover images and use them for data-mining tasks. This architecture involves the use of a Web browser to gain access to images stored in a database through a Java Applet. The architecture enables the client to access and process the images independently from the platform. The data-mining operations with a high computational cost are performed in a network of workstations (NOW) of Sun UltraSparc II. The requirements of the client are handled to the server, which executes in parallel the algorithm at the processing network by means of message-passing libraries [9].
- Distributed architectures are a good alternative to the supercomputers in terms of

processing power when executing high-cost computational tasks. Another architecture based on message passing is the proposal of Li, Veeravalli and Ko, (Li et al, 2003) that uses the PVM (Parallel Virtual Machine) library (http://www.csm.ornl.gov/pvm) to pass communication messages to and from the processors of various workstations. This approach is based on the division of the image into several parts in order to be distributed among the network nodes and processed afterwards; the approach of He, Wu, Liu and Zheng (He et al, 2003) explores the best way to distribute the data among the different processors.

Among all the aforementioned architectures, only he Diamond Eye developed by NASA achieves distributed processing using the Web browsers as front-end by means of Java applets. However, this system is very specific and does not allow the integration of different types of tools. A framework is therefore needed for the integration of heterogeneous tools into an information system that can support high computational costs through the Internet.

PROPOSED ARCHITECTURE

Considering the vast amount of existing medical imaging modalities and their respective processing needs, the proposed architecture had to be independent from both software and hardware and integrate several image processing algorithms. Our architecture provides access to the processing services through a Web interface. The present work proposes a framework for the development of tools that are able to provide a medical team with all the processing power required for high cost visualization, planning, and simulation tasks by means of a remote server. These tasks can be performed independently from a physical location, since only an Internet connection and browser are needed.

This section describes, from two different viewpoints, a solution for the integration of processing algorithms for biomedical digital imaging into Web systems. The first perspective is that of the physical placement of each element, whereas the second perspective focuses on the logical structure of the architecture.

Physical Framework Architecture

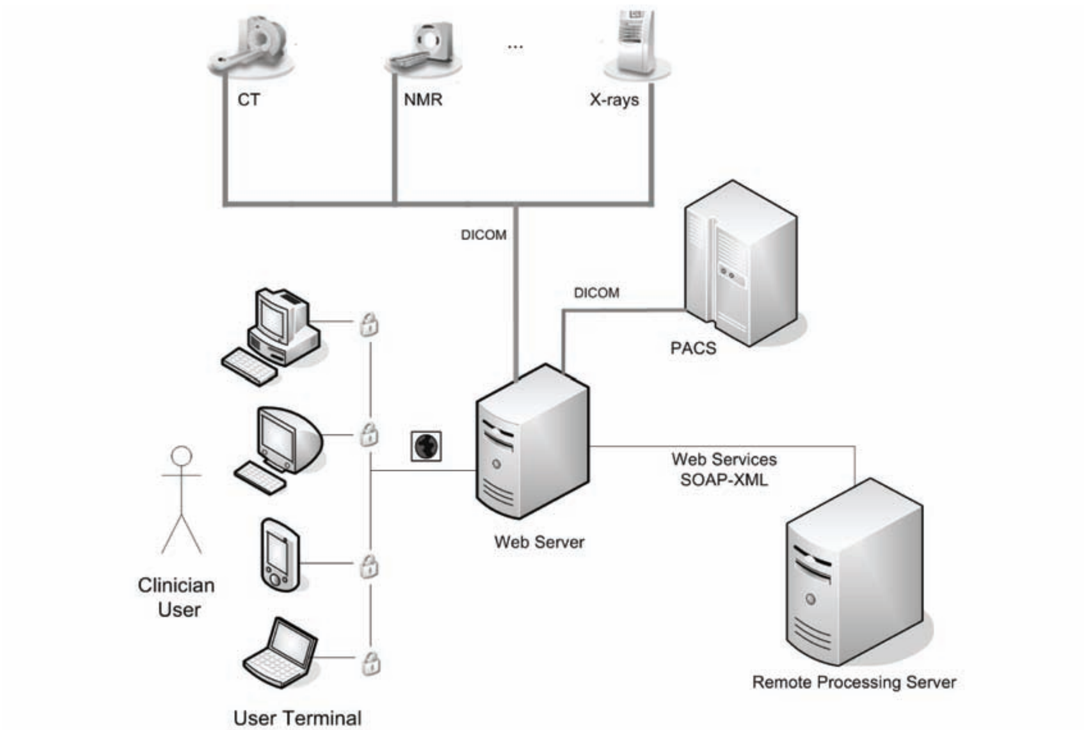
The main parts of the architecture are the following: the user terminal, the web server, and the remote processing server (Figure 1).

The user terminal is located at the Web browser and is integrated in an information system, whose data could be used for digital image processing operations. Once the user has selected the images that will be processed, the tools and the possible environments for digital processing are shown. An applet is executed when selecting a tool; this applet involves a display and a simple processing kernel and shows the images and processing options.

The Web Server is in charge of four fundamental tasks: it has to communicate with the kernel of the display for the transfer of images and other patient-associated data, it communicates the image information system for independently retrieving images and its associated information from various data sources, it performs the digital processing of the images with high computational requirements (remote processing), and it gives access to the different remote processing servers.

The use of remote processing servers offers the following advantages: the distribution of computational loads related to the digital processing, the integration of algorithms developed with different languages, the calculus transparency (how and where) for the developer thanks to Web access, and lastly, a higher processing capability. The architecture provides a uniform access through Web services and has a high scalability, which

Figure 1. Physical framework architecture



means that multiple queries can be received and processed at the cluster and that results can rapidly be returned by means of the distributed computation paradigm (Foster, 1999).

Logical Framework Architecture

The tools and components are defined so as to obtain a homogeneous and configurable interface.

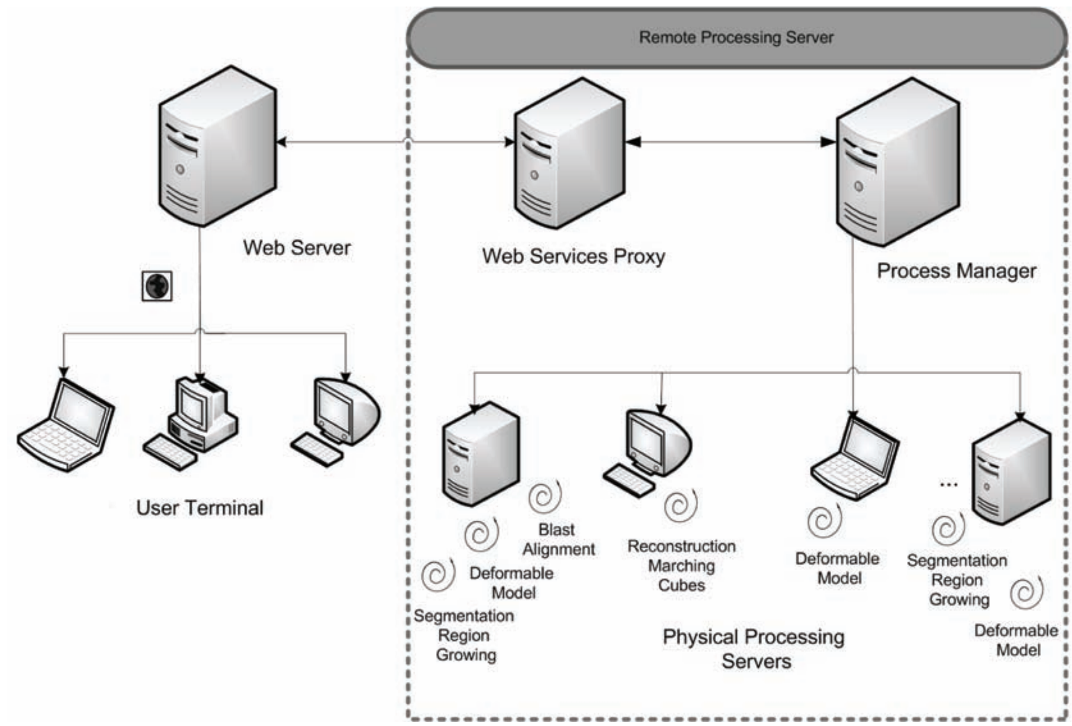
Tools: A tool comprises the set of specific functions that are needed to work with a certain type of image, i.e for each possible environment for digital image processing. For instance, the functions for working with hemodynamics imaging are not the same than the ones used for oncology imaging; however, there might be common functions for both tools. Each tool has one or more components.

Components: Each component performs a specific function in the system, ranging from information management to digital image processing, with optional forms for the modification of processing parameters that are visualized at the applet. An example of a component is the function that changes the brightness and contrast of an image. The components have two different parts attending the place where they are executed: one of them inside the applet of the client's Web browser, and the other inside the application server, where it processes and manages the remote information. When building these two parts, interfaces must be defined for the good functioning of the parts.

Each component usually works with one or more DIP, such as for instance the segmentation of a hemodynamics image. Depending on the complexity of such algorithms, they will be located inside the applet, inside the application server or inside the remote processing server.

Local processing: If the processing algorithms have simple computational requirements, their execution is performed at the kernel of the client

Figure 2. Remote processing server detail



applet, located at the user terminal. This type of processing is known as local processing.

Application server processing: This second type of processing is especially indicated for algorithms of medium complexity, which will be executed by the application server. Each component is divided into two parts: the local part at the user browser and the remote part at the application server. The algorithm parameters are established at the local part of the component. When executing the processing, a request is sent to the application server through the tool, the kernel of the display, and the applet. After arriving to the servlet -where the component that has to be executed is identified- the remote component of the algorithm will be invoked to execute the algorithm and return the result.

Remote server processing: Finally, the remote processing servers are used for load distribution and to provide support to the algorithms that are developed with various programming languages. In this case, the remote part of the component -located at the application server- sends the request to the Web service, where the algorithm is executed. The result is sent back to the remote part and, from there, to the display. The different parts of the remote processing server can be observed in Figure 2.

A remote processing server model with three parts is built as follows: the first part, the web services proxy, collects the external processing web requests that come from the information system. These requests are sent to another server where the processing manager is located and where they are directed in accordance with both, the needed processing type and the original object that made the request to the web service. The third part is represented by the physical remote processing servers, which are able to perform one or more different intensive processing algorithms. The remote object manager instantiates a remote processing object on the subsequent server in charge of executing the needed processing algorithm, keeping the result at the local memory of the machine where the algorithm is being executed, and returning that result when needed.

There are two reasons for dividing the remote processing server into three parts. Firstly, processing is usually quite costly and may collapse the reception, so we must separate the reception of the web server queries from the server that performs the intensive processing Secondly, the objects that are instantiated on the web server have no state, since every time a remote call is made from a web server, an object is instantiated; this object disappears as soon as it returns (web services behaviour). This fact reduces the functionality, because it does not allow the interaction with the remote object, but also acts as a call to a function that replies with a result. This architecture provides the web services with a virtual state that allows us to carry out several calls on the same object to assign parameters, modify them during the execution, and test the processing status.

The web services proxy implements only one processing method. The parameters of this method are an identifier of the object that invokes the web service, the operation type realised at the processing, and a list of parameters needed for performing that operation. This method invokes an operation from the remote object hosted at the processing manager that controls the processing objects. Distributing the processing manager among several machines provides a higher failure tolerance and a simpler maintenance, since each machine carries out only one function.

The object manager instantiates the processing objects that are needed to execute the processing algorithm required by the web services proxy; it also distributes the load among the different physical servers and it manages the security of the transactions. At the first call of an algorithm, the object manager instantiates a new object on one of the processing servers and then all the processing calls are directed towards that object.

Finally, the processing servers execute one or more processing algorithms. The remote object manager determines which physical processing server is more suitable for executing the new processing, according to the algorithms that every server has and the processor load at that moment.

IMPLEMENTATION

This section describes the technologies that were used to implement the architecture. The user terminal was developed with Java applets because of their multiplatform nature and also because it is a common solution for providing a web environment with processing capacities (Laird et al, 2003). In this part, where the local processing takes place, the algorithms must be developed with Java and with the option of using the advanced API for image processing of JAI (Java Advanced Imaging) (http://java.sun.com/products/java-media/jai).

The application server was developed with the J2EE platform, because it is portable, scalable, and safe, and because it uses open standards. The implementation that was used for J2EE is the Apache Tomcat 5.0.28. Since in this part the remote processing can be performed, we can integrate the developed processing algorithms that use either Java or C. Link libraries known as Java Native Interface (JNI) are used for algorithms developed with C.

The communication with the remote processing servers was established by means of web services, whose hardware and software are platform independent, which widens the range of implementation possibilities for the various remote processing servers. The algorithms developed with Java or C could be integrated using the same scheme for the web server. If the algorithm is developed with another language, or if the used technology is different, the algorithm's developing framework will only have to be supported by web services.

The validity of the remote processing system is proved by implementing two remote processing servers, one developed with Apache AXIS Java libraries, the other with a .NET Framework. In this case, the previously proposed remote processing server was implemented. An ideal processing scenario would imply three or more machines for the processing server: the first machine could have Internet Information Services (IIS), to collect the requests from the application server, or a stand-alone application that may require this type of processing by means of web services; the second machine would host the processing manager, and the remaining machines would house the specific processing servers. The technology used to inter-communicate the proxy with the object manager and the latter with the processing servers is .NET Remoting over TCP. In all these servers .NET framework must be installed. The use of .NET consists in integrating the developed algorithms by means of any .NET-supported language such as Visual Basic, C#, Visual C++, etc.

The standard network topology implies one or more J2EE application servers that respond to the requests of the client's applets. The remote processing server will need one or more machines with Internet Information Services (IIS) to serve the web services requests. These are the only machines that would have to be provided with an external connection. Security will be implemented by means of SSL certificates provided by the IIS (Seely, 2002), which warrant the Internet transaction security. On the one hand, the LAN network, which contains the IIS, has a machine provided with a *ProcessManager* for client control and the processing types of the system. The related data of previous versions will remain in a data base and as such allow several machines to provide this service. On the other hand, there exists a network of physical processing servers where every machine can execute one or more algorithms of intensive processing.

Integration into an Information System

The architecture was designed for to be easily integrated into an image information system. In this case, it was integrated into a biomedical imaging information system known as Web-SMIIS that is part of the SMIIS project (Pereira, 2003). The SMIIS is essentially a PACS for the retrieval of information from any modality that might support the DICOM standard, and the subsequent storage of that information into a data base for consultation. The SMIIS was developed by the Centre for Medical Informatics and Radiological Diagnosis (IMEDIR) of the University of A Coruña (Spain).

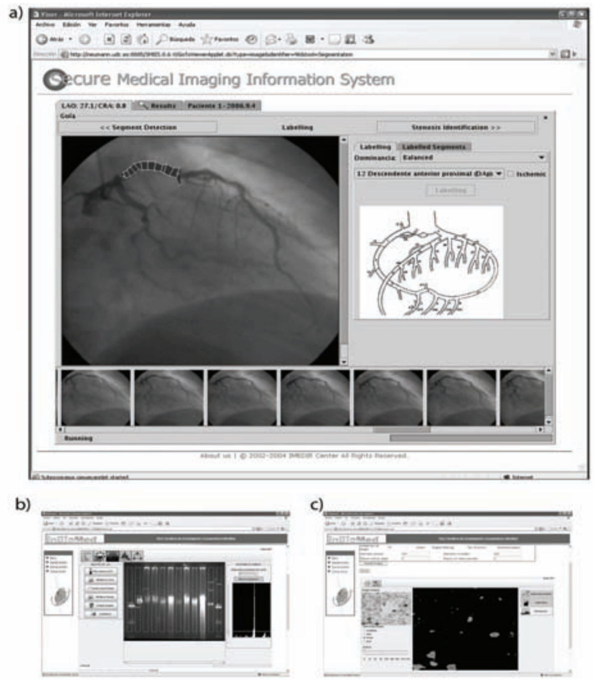
The integration between the two systems is focused on a point where the architecture has to obtain the images. This place depends on each information system. In the Web-SMIIS, the facade "*QueryFacadeDelegateFactory*" is the access to the SMIIS.

Also, this architecture could be integrated into any PACS DICOM thanks to a module that allows the extension of the system's functionality in order to achieve its compatibility with the DICOM standard and, more specifically, with the storage query/retrieve services.

RESULTS

This architecture was implemented in two Spanish hospitals, the *Complejo Hospitalario Universitario Juan Canalejo* and the *Instituto Médico Quirurgico San Rafael* in A Coruña. The first is the most important hospital of the city and a centre of reference for a geographic area of more than 500.000 people. The second is one of the most important private hospitals of A Coruña. The processing architecture is currently being validated by a group of 7 medical experts of the Hemodynamics Service of the Juan Canalejo Hospital, which carries out 3.000 catheterisms

Figure 3. (a) Stenosis detection tool (b) electrophoresis gel analysis tool (c) inmunohistochemical count tool



each year. The processing architecture is currently available in the radiology service of the San Rafael hospital.

Validation protocols are long and complex. The hemodynamics unit of the Juan Canalejo Hospital validated a total of 63 angiographs in groups of 2 to 3 members; the San Rafael Hospital validated 213 radiology studies (TC, MRI, medical ultrasonography, etc.) in groups of 3 members each.

We developed two tools for the semi-automatic analysis of angiographs in collaboration with the clinicians of the Hemodynamics Unit of Juan Canalejo in order to establish a score pattern for coronary stenosis. The first tool uses for segmentation tracking techniques (O'Brien and Ezquerra, 1994) (NEzquerra et al, 1998), the second tool uses morphological operators and techniques of region growth (Haris, 1999)(Kirbas, 2003). Figure 3a shows a screen capture of this tool.

This architecture was also used for tool development in the cooperative thematic research network INBIOMED (Pérez et al, 2005). With the collaboration of the Pharmacology Group from the University of Santiago de Compostela (Spain), a tool was developed for the analysis of protein and DNA electrophoresis gel (Figures 3b). It allows the application of low cost image preprocessing algorithms such as low-pass filtering, image-enhance filter, image rotation operator, etc., as well as the semiautomatic detection and analysis of the lanes and bands that contain this kind of image in order to obtain the protein weight represented by the relative position of the bands in each lane. Another tool that was developed by the INBIOMED network provides a fast and user-friendly cell count for immunohistochemical images using adaptative thresholding (Chow and Kaneko, 1972)(Chan et al, 1998) (figure 3c), applying not only low-cost image processing to the client side, but also algorithms with a high computational cost that are executed at a separate

Table 1. Hospital and validation data

	CHU Juan Canalejo	IMQ San Rafael
Beds	1.430	148
Total annual external consultations	672.295	44.310

Implantation and Validation	Hemodynamics Service	Radiology Service
Service Volume	2.896 annual catheterisms	34.700 radiological tests
Validation team	7 persons	3 persons
Number of Tests	63 Validated studies	231 Validated studies

processing server that communicates with the system through Web services. (Table 1)

Finally, we developed a tool for the segmentation and subsequent reconstruction of three-dimensional medical image volumes. It uses algorithms with a high computational cost such as 3D region growth to segmentate the desired regions and marching cubes to reconstruct and visualize these regions in a Java applet on an internet browser. Both techniques are implemented in the remote processing server because of their high computational cost.

Table 2 shows the test results for the proposed architecture. Three high computational cost tests focused on development: cell counting in high resolution color images, segmentation of a skull in a CT set of 106 512x512 slices, using region growth, and reconstruction of this segmentation with marching cubes algorithms (Lorensen and Cline, 1987) (the processing time does not count image loading time). The tests were carried out according to three approaches: an applet, a stand-alone application, and the proposed architecture (10 processing units), with one, five, and twenty requests. A normal PC (Pentium IV 3GHz with 1GB RAM) was used in the one-machine test.

CONCLUSION

We propose a system that allows medical experts to analyze patient data through a web browser by integrating processing algorithms of biomedical imaging into web-based information systems.

The design is based on the use of both design and architectural patterns and provides the

Table 2. Test results

	Cell counting	Region growing	Marching cubes
Applet	40.8 s	(not enough memory)	(not enough memory)
Stand-alone application	12.6 s	19.3 s	5.6 s
Proposed architecture 1 request	15.3 s	22.1 s	6.8 s
Proposed architecture 5 request	22.1 s (4.4 s/req)	26.8 s (5.3 s/ req)	8.2 s (1.64 s/ req)
Proposed architecture 20 request	47.6 s (2.3 s/ req)	56.1 s (2.8 s/ req)	18.2 s (0.91 s/ req)

simple integration of this kind of architecture with information systems carried out under a "model-view-controller" paradigm such as SMIIS. Also, the design of new processing tools based on the "view-tool-component" model allows the developers of digital processing algorithms to easily integrate them and obtain new components and tools.

The remote processing server allows the incorporation of the architecture into new types of distributed systems, since it provides the developer with a façade that hides the placement, the functioning, and the situation of each specific remote processing server; it also provides a common interface and only one entry point for all the processing algorithms implemented in the system.

Another advantage of the remote processing server architecture is its communication with the application server by means of web services, because this implies remote processing through the Internet without any port redirection problems, firewalls, etc.; it also means that the application server may be located in a different place from the network of processing servers.

From the point of view of the user, we have achieved transparency with regard to the execution of the process. The clinician carries out data analysis and processing, regardless of whether the processing is simple and can be done at the local machine with the Web browser, or it is expensive and implies the joint work of several equipments.

ACKNOWLEDGMENT

This work was supported in part by the Spanish Ministry of Education and Science (Ref TIC2003-07593, TIN2006-13274), Ministry of the Treasury (PROLIT/SP1.E.194103), the INBIOMED network (Ref G03/160) financed by the Carlos III Health Institute (FIS-PI061524), and grants from the General Directorate of Research of the Xunta de Galicia (Ref. KEY TERMS

Client-Server Architecture: The most fundamental distributed architecture. A client-server architecture is simply a client process that request services from a server process.

Common Object Request Broker Architecture (CORBA): Is a distributed object architecture defined by the Object Management Group. This architecture provides an interface that invokes other CORBA objects across a network.

Digital Imaging and Communication in Medicine (DICOM): A standard format and application protocol developed by the NEMA (National Electrical Manufacturers Association) to communicate systems over TCP. This protocol allows the integration of PACS, workstations, and TC, MNR, and other image scanners.

J2EE: Java 2 Enterprise Edition is a widely used platform for server programming in Java language, used to deploy distributed multi-tier Java software running in an application server. It is also known as Java EE in versions 1.5 and following.

Java Advanced Image (JAI): Is an image-processing toolbox, developed by Sun, that provides an object-oriented interface for the support of high-level programming models that allow images to be easily manipulated in Java applications.

Marching Cubes: A computer graphics algorithm for the extraction of a polygonal mesh of a set of volumetric data.

.Net Remoting: A distributed-object architecture by Microsoft to develop distributed applications over Microsoft platforms.

Network of Workstations (NoW): Is a computer network that connects several computer workstations with special software forming a cluster, to act as a distributed supercomputer on a building-wide scale.

Parallel Virtual Machine (PVM): Is a software package that allows a heterogeneous collection of computers hooked together by a network to be used as a single large parallel computer.

Picture Archive and Communication System (PACS): A storage system composed by different computers and networks dedicated to the storage and retrieval of medical images.

Platform-Independent: An application that can be run on many different server platforms, e.g. Java.

Region Growing: A segmentation technique based on the similarity of adjacent pixels. A region is started with a single pixel (seed pixel) and the adjacent pixels are added to the current region if they are similar to the region.

SSL: A secure socket layer is a secure protocol that provides secure communication over the internet based on cryptographic techniques. At present it is also known as TLS (Transport Layer Security)

Transmission Control Protocol/Internet protocol (TCP-IP): Is the basic family of network protocols for the Internet.

Web Services: Software system designed to support interoperable machine to machine interaction over web. It uses SOAP protocol and XML messages to receive request and offer responses.

Chapter 8.4
Social Media Marketing:
Web X.0 of Opportunities

Lemi Baruh
Kadir Has University, Turkey

ABSTRACT

In recent years social media applications, which enable consumers to contribute to the world of online content, have grown in popularity. However, this growth is yet to be transformed into a sustainable commercial model. Starting with a brief overview of existing online advertising models, this chapter discusses the opportunities available for advertisers trying to reach consumers through social media. The chapter focuses on viral marketing as a viable option for marketers, reviews recent viral marketing campaigns, and offers recommendations for a successful implementation of social media marketing. In conclusion, the author examines future trends regarding the utilization of the emerging Semantic Web in marketing online.

DOI: 10.4018/978-1-60566-368-5.ch004

INTRODUCTION

The brief history of the World Wide Web is filled with stories of unprecedented commercial success as well as shattered dreams of hopeful online entrepreneurs. It should not be surprising that, just as their predecessors, Web 2.0 and social media also bring about important questions regarding their sustainability. On the one hand, since 2006, social media sites have been growing in number and popularity (Boyd & Ellison, 2007). For example, according to comScore, a leading Internet information provider, as of December 2007 Facebook had close to 98 million unique visitors, and Fox Interactive Media, including MySpace, had more than 150 million. Similarly, recent years have seen a phenomenal growth in the popularity of weblogs (blogs): in 2007 every day, 175,000 new blogs were added to an estimated 67 million blogs that were already up and running (as cited in Rappaport, 2007). On the other hand, skeptics voice their belief that social media, despite their current popularity, may not have the staying power (“MySpace, Facebook and Other Social Networking Sites,” 2006).

An important component of skeptics’ concerns about the sustainability of social media pertains to the fact that there are no agreed upon ways of monetizing the rising popularity of social media (Allison, 2007; Hall, 2007). Perhaps, the most telling example of this problem is Facebook. Despite having a market value of around $15 billion, Facebook’s 2007 revenue was $150 million (McCarthy, 2008) – a considerably small share of the $21 billion online advertising industry. Then, the question of whether social media will be more than just a fad boils down to advertisers’ ability to utilize the unique opportunities presented by social media. Although advertisers and social media entrepreneurs are yet to agree on a marketing model for social media, recent discussions point to several important requirements that a successful model should accommodate. Given the decentralized architecture of the Internet in general and social media in particular, a central tenet of these recent debates concerns the relative merits of more conventional advertising methods and word of mouth (or word of “mouse”) based marketing approaches that cede control to the consumers.

In the light of these debates, this chapter will start by summarizing online advertising methods. After this brief summary, the chapter will focus on the opportunities and challenges for online marketers that are brought about by the development of social media. Finally, the chapter will discuss viral marketing and integrated marketing communication principles to provide a roadmap for realizing the financial and marketing potential of Web 2.0.

BACKGROUND

Online Advertising

In its most traditional sense, *advertising* is defined as a paid form of communication appearing in media, usually with the purpose of reaching a large number of potential customers. Since 1993, when CERN announced that the World Wide Web would be available to anyone free of charge, advertisers experimented with different methods of reaching consumers online. Unsurprisingly, the first reaction of advertisers was to treat the World Wide Web as a natural extension of traditional media, such as newspapers and television. And, just as in conventional mass media, early online advertising methods, such as banners, pop-ups and interstitials, were characterized by intrusiveness and adoption of a one-way stimulus-response model within which information flows from the advertiser to the customer (McCoy, Everard, Polak, & Galletta, 2007; Rappaport, 2007).

However, even in the early years of online advertising, signs of what was to come in interactive marketing were revealed. Shortly after banners became a popular online advertising method in 1994, keyword-activated “smart banners” were introduced. What set smart banners apart from their predecessors was that the contents of the banners were personalized in response to the search words entered by the users. As such, smart banners were one of the first examples of how content variability in new media (Manovich, 2001) can be utilized to customize information to consumers’ needs (Faber, Lee & Nana 2007).

Customization and Message Congruence in Interactive Media

As noted by several researchers, content variability and the consequent ability to customize content according to the needs of the consumer are made possible by the interactive capabilities of new media (Baruh, 2007; Faber et al., 2007).

Two important characteristics of interactive media are the ability to facilitate a two-way flow of communication and the related ability to track and store every bit of information about how consumers use a system (McCallister & Turow, 2002). Real-time information about how consumers use a medium, especially when combined with other data through data mining, enables marketers to extract profiles about individuals that can then be used to tailor messages and products.

The ultimate aim of this process is to target different consumer groups with specific messages that can tie a product to their informational needs, lifestyles or predispositions. Extant literature on online targeting suggests that consumers will be more receptive to messages that are tailored as such (McCoy et al. 2007; Robinson, Wyscocka, & Hand, 2007). To a large extent, this higher receptivity is the result of being able to promote the "right" product, at the "right" time and place and the "right" tone. A case in point that supports these research findings is the success of Google's AdWords, which accounts for 40% of online advertising spending. The premise of AdWords is that the marketers can reach motivated consumers by providing them with contextual advertising messages congruent with their online keyword searches (and presumably, their interests). Similarly, a widely known feature of online vendors such as Amazon.com is their customized product recommendation systems. The recommendation system these online vendors utilize is based on a data mining system called *market-basket analysis* (also called *association discovery*). The premise of this system is that the marketer can create cross-selling opportunities by identifying the product types that a customer would be interested in (e.g., microwave popcorn) on the basis of other products that he or she has already purchased or is purchasing (e.g., a DVD movie). As such, what the market-basket analysis algorithm does is to identify product clusters that are purchased together or sequentially using the product purchasing history of customers whose tastes are similar to a specific customer.

ONE STEP FURTHER: WEB 2.0 OF OPPORTUNITIES

Customization and Data from Social Media

As can be inferred from the discussion above, collecting information about consumers is an important prerequisite of customizing advertising messages in accordance with the informational needs and lifestyles of consumers. Certainly, data about individuals' online media consumption and purchasing behavior, especially when combined with other sources of data such as credit history, provide marketers with an unprecedented capability to not only determine which customers to target (and avoid) but also when and how to target them.

Within this context, social network sites, such as Facebook, MySpace or LinkedIn, have a potential to extend what is already a large pool of data about consumers. Such social network sites are designed to allow users to create personal profiles and connect with other users, friends or strangers. And through the creation and perennial updating of their profiles, users of social network sites actively participate in the dissemination of information about themselves (Andrejevic, 2007; Solove, 2007). The types of information users of social network sites disclose include: information about their hobbies, interests, likes and dislikes, whom they associate with, a dinner they had a couple of days ago and, sometimes, disturbingly private details about their social and sexual lives. Blogs, another highly popular form of social media, are no different from social network websites. As Solove (2007) points out, any topic, any issue and any personal experience are fair game for more than 60 million bloggers around the world.

The massive quantities of data that social media users reveal online are not left untapped by media companies and marketers. For example, MySpace has recently begun an effort to mine data from its more than 100 million users in order to better target advertising messages. Named as MySpace HyperTargetting, the system initially began mining data about general interest categories, such as sports and gaming, and is now further dividing interests into thousands of subcategories (Morrisey, 2007).

The Community Touch

An important point to note with respect to the types of data available in social media is that the digital goldmine of information is not simply a more detailed version of data collected about consumers' interests and behaviors in other forms of interactive media. Rather, in social media, the available data contain unprecedented details about the network affinities of users. The data about the network affinities of users can be utilized at two levels. First, through the "tell me about your friends and I'll tell you about yourself" principle, marketers can make further refinements to consumers' profiles based on the interests shared by members of the communities they belong to. Secondly, information about the communities that an individual belongs to can be used to identify the paths through which they can be reached.

Recent marketing techniques devised by online vendors and social media outlets illustrate how information about social affinities can be used to reach consumers. For example, Amazon.com's iLike application, a music service that markets new music and concerts to interested listeners, works by scanning the music libraries of its subscribers. The service connects like-minded listeners and promotes new music to users through add-ons such as Facebook's iLike widget. Similarly, Facebook's own Beacon platform tracks purchases Facebook users make on partnering online vendors and then informs users' networks about the recent purchase (Klaassen & Creamer, 2007; Thompson, 2007; Tsai, 2008). In addition to leveraging existing social networks to disseminate marketing messages, some software applications, for example, Stealth Friend Finder automatically generate massive and targeted Facebook Friend Requests to directly connect with the consumers.

Web 2.0 of Opportunities: Viral Marketing in Social Media

These examples of social targeting pinpoint the direction that marketing in social media can take. Rather than being an advertising distribution system, Beacon is a viral marketing tool that lets community members know what their co-members have purchased. In other words, with the Beacon system, the consumer, through the publication of his/her purchasing decision, assumes the role of an influencer. Subramani and Rajagopalan (2003) suggest that consumers may assume such a role either passively or actively. In the passive form, the consumer spreads the word simply by using or purchasing a product (as is the case when an e-mail from a Blackberry user contains a message saying the e-mail was sent using a Blackberry account). On the other hand, active viral marketing requires that consumers participate in the message dissemination process by contacting other potential customers (Clow & Baack, 2007).

An important criticism of passive viral marketing systems in social media is that they fail to utilize an important characteristic of Web 2.0 in general and social media in particular. Instead of being a passive consumer of readily available content, Web 2.0 users are participants in both the creation and dissemination of content. Accordingly, despite utilizing social graphs to target messages more effectively, the "your friend just bought this book from Amazon.com" message is nevertheless an advertising method that affords the consumer very little power as a potential source of influence (Anderson, 2006; Windley, 2007).

Considered from this perspective, a more appropriate way of utilizing the viral potential of social media users is to invite them to actively participate in promoting the product. First, existing research shows that close to a quarter of users of online social networks, such as Facebook, use these sites to influence other users (Webb, 2007). Second, as evidenced by Facebook users' negative reaction to Beacon, social network sites are relatively intimate environments and advertising intrusion (especially given an overall mistrust for advertising messages) is not welcome (Clemons, Barnett, & Appadurai, 2007; Gillin, 2007; Hall, 2007). In contrast, 94% of online social network users find product recommendations from friends to be at least very worthwhile to listen to (MacKeltworth, 2007). This finding is not surprising since recommendations coming from friends, family members, or colleagues are more likely to be trustworthy and relevant to one's needs (Clemons et al., 2007). In fact, according to a recent survey, along with the reputation of the manufacturer, recommendations from friends and family members are the biggest factor that influences purchasing decisions made by individuals (Klaassen & Creamer, 2007). Third, thanks to synchronous connections between multiple users, a computer-mediated word of mouth can reach a larger number of people than word of mouth in the brick and mortar world.

As briefly mentioned before, in addition to these three important advantages of inviting social media users to actively disseminate marketing messages, product information, or recommendations, social media also provide marketers with an unprecedented capability to identify the individuals who would be the best candidates in a social network to act as viral marketers. Domingos (2005) suggests that in addition to actually liking a product, a suitable viral marketing candidate should have high connectivity and should be powerful as a source of influence. Using social network analyses (Hanneman & Riddle, 2005; Scott, 2000; Wasserman & Faust, 1995), data regarding personal affiliations and social network memberships can be utilized to identify opinion leaders ("hubs") who are central to and powerful in a given network.

Recently, there have been several attempts to apply social network analysis to social media to identify social network influencers. For example, Spertus, Sahami, and Büyükkökten (2005) used network data from Orkut.com to identify members who could be used to recommend new communities to users. Similarly, in a study of Flickr and Yahoo360 networks, Kumar, Novak and Tomkins (2006) were able to distinguish between passive users and active inviters that contributed to the extension of the network. And recently, MySpace announced that it is constructing an "influencer" option for advertisers who could be interested in reaching users with active and large networks. To identify potential influencers, MySpace will use data regarding users' group memberships and interests, their friends' interests, level of network activity in a given network and other factors (Morrissey, 2007).

The Integrated Marketing Communications Perspective

In 1976, Wayne DeLozier suggested that marketing communication was a process of creating an integrated group of stimuli with the purpose of evoking a set of desired responses. According to this integrated marketing communications perspective, which has been adopted by many companies since the 1980's, rather than being considered in isolation from one another, each component of the marketing mix should be coordinated to present a unified image to consumers.

Considered from this perspective, fulfilling the viral marketing promise of Web 2.0 and social media requires that the viral marketing effort be part of a greater scheme of corporate communications. In other words, rather than merely focusing on spreading the word, the viral marketing effort should fit the brand personality (Webb, 2007). A particular case illustrating this point is the "Top This TV Challenge" campaign of Heinz®. In this campaign, Heinz® invited consumers to produce 30-second TV commercials for Heinz® Ketchup and submit the commercials on YouTube. The winner of the contest, determined first by a panel of judges and then by the votes of consumers, was awarded $57,000 and a chance to get the commercial aired on national television. The premise of the campaign was not only that it fit the "fun" brand image of Heinz® Ketchup but also that the consumers would play a crucial role in disseminating Heinz Ketchup's name. Just as intended, many of the 4,000 qualified contestants who posted their videos on YouTube (as required) also created MySpace and Facebook pages promoting their own videos and consequently Heinz Ketchup.

Another example illustrating the connection between viral marketing and an integrated marketing communications approach that provides a fit between the marketing campaign and the organizational image is the "Download Day" organized by Mozilla Firefox in June 2008. Mozilla is a not for profit organization that is mostly known for its Firefox Web Browser (a challenger of the market leader, Internet Explorer). The organization is a self-proclaimed open source project that publicly shares the source codes of their own software for the development of new Internet applications. Unlike its major competitors, such as Internet Explorer and Safari, the Firefox Web Browser is positioned as an "organic browser" that has been developed through a collaborative process whereby thousands of software developers – the majority of which are not employed by Mozilla – contribute to the software. Likewise, the dissemination of Firefox largely relies on volunteers "spreading" the software.

In June 2008, Mozilla created a Download Day event to promote the third version of its Firefox Web Browser. The purpose of the Download Day was to set a world record in the number of downloads in 24 hours. To inform would-be users about the event, Mozilla heavily utilized social media and viral marketing. Following the initial announcement, the word of mouth about the Download Day first quickly spread through social news aggregators such as Digg™ and Reddit.com. Then, the links in the social news aggregators forwarded interested users to the Download Day homepage. In addition to asking individuals to pledge to download Firefox on Download Day and providing an update on the number of individuals who pledged to download, the homepage also invited them to engage in viral marketing by inviting their social networks to the event via Facebook, Bebo and MySpace, promoting the event on microblogging Twitter-like websites or organizing "Download Fests" on university campuses.

These two examples provide important insights regarding the criteria for a successful viral marketing campaign online (and in social media):

1. **Campaign-Organizational Image Congruence:** In the Download Day example, the event, the promoted goal (setting a world record) and the method of dissemination of the information of the event (through social media) were in line with Mozilla's overall image as a non-corporate, decentralized and innovative organization that relies on volunteers and users for its promotion as well as software development. Similarly, the "Top This TV Challenge" campaign of Heinz® fits the "fun" brand image of Heinz® Ketchup.
2. **Inciting Virality and Buzz:** This is the key for creating a pull rather than inducing a push in an organization's marketing campaign. An attractive event (in this case a world record setting event) or a message is a crucial component in developing an organic viral marketing process. The ability to create buzz through the event will also increase the chances that the viral marketing campaign will supplement other marketing communication goals: such as, providing

material for other promotional efforts or getting coverage in traditional media—the latter being especially important for Firefox given that Mozilla does not have a centrally controlled advertising budget to spend on conventional media. For example, the overwhelming interest in the Top This TV Challenge (with 5.2 million views) also helped create publicity for the company in the mainstream media and prompted Heinz® to repeat the challenge in 2008.

3. **Getting Consumers to be Personally Invested:** Mozilla's Download Day emphasized not only the possibility of a world record but that the consumers would be an integral part of this unique success. In this case, the prospects of being a part of a possible Guinness World Record-setting activity may have increased the chances that consumers identify with (and are invested in) not only the product or the brand but also the success of the campaign. Perhaps, for the contestants in the Heinz® Top This TV Challenge, the personal investment was even higher because their own success (in terms of getting enough votes to win the contest) partly depended on the popular votes they would get from other consumers.
4. **Creating Levels of Viral Involvement:** In terms of options available for viral marketing, social media not only expand the available options but also create the possibility of multiple levels of viral involvement. For example, in the Heinz® Top This TV Challenge, the level of viral activity of a contestant that promotes his/her video will naturally be higher than a regular YouTube user who happens to come across a challenger's video that is worth sharing with friends. The Mozilla's Download Day event, on the other hand, systematically utilized the social media (and other venues) to create tiers of consumer involvement. For example, an enthusiastic Firefox user could go as far as organizing a download festival whereas a regular user of Facebook or MySpace could invite friends to pledge for the download on the Mozilla's Download Day homepage.

FUTURE TRENDS

As discussed in the preceding sections, a central tenet of the debates regarding the marketing potential of social media pertains to the balance that needs to be struck between the efficiency of automatic recommendation systems and the organic involvement created by the real community touch of viral marketing campaigns that invite consumers to actively participate in the dissemination of the marketing messages. On the one hand, systems such as Facebook's Beacon platform and MySpace's "influencer" option promise to deliver large-scale, automated word of mouth that can expand the reach of viral marketing campaigns. However, the perceived intrusiveness of such systems, as well as their tendency to use consumers as passive hubs to automatically relay marketing messages, may call into question the true virality of such advertising efforts, consequently reducing their appeal for consumers.

Recent discussions regarding "Web 3.0" and the future of the Internet may point to the direction that this uneasy relationship between virality and automatic customization may take. Despite frequent disagreements regarding the definition of Web 3.0, an increasing number of commentators have started to use the concept interchangeably with the Semantic Web – a set of technologies that enable software agents to understand, interpret and extract knowledge from information, making it possible for them to complete "sophisticated tasks for users" (Berners-Lee, Hendler & Lassila, 2001). Michael Bloch provides a simple example explaining how the Semantic Web would work:

You want to go out to dinner…and your car is in the shop… You issue a command for the agent to search for a restaurant serving Indian food *within a 10-mile radius…You want a restaurant that has a 4 star rating issued by a well-known restaurant critic. Furthermore, you want the table booked and a cab to pick you up from your place. Additionally you want a call to be made to your phone once that's all done; but you don't want to be disturbed by the call as you'll be in a meeting - just for the reservation details added to your phone organizer. (Bloch, 2007)*

As this example suggests, the Semantic Web is more than a compilation of web pages. Rather, it is a network of systems and databases that can communicate with each other to perform tasks on an individual's behalf. Moreover, as recent developments suggest, the Semantic Web will have the potential for subtler customization of information in accordance with the cognitive (and perhaps emotional) styles/needs of consumers. For example, an article by Hauser, Urban, Liberali and Braun (forthcoming) from MIT's Sloan School of Management announces an algorithm that uses clickstream data to morph the website content and format to the cognitive style of its users.

As evidenced by recently developed semantic web advertising applications (such as *Semantic-Match*™ – a semantic advertising platform that utilizes a natural language processing algorithm to understand content and sentiments and target advertising accordingly), when applied to online advertising, semantic capabilities can enhance customization, decrease errors that are associated with keyword targeted advertising and provide a more conversational interaction between the advertiser and the consumer. With respect to viral marketing, such advancements in language processing and customization can address an important shortcoming of passive virality by making it more personal. Whereas social network analyses aid the identification of hubs that can act as active viral marketers, improvements in natural language processing can prove beneficial in terms of understanding the communicative processes and dynamics within a social network. This information can help the marketing organization create different strategies to reach various potential hubs, create levels of viral involvement depending on the depth and the context of the communicative processes between network members, and customize the webpage that potential customers arrive at as a result of the viral marketing effort.

CONCLUSION

In recent years, Web 2.0 applications that enable web users to contribute to the world of online content have grown in popularity. In 2008, the Top 10 most frequently visited web site list of Alexa Internet – a web traffic information service – consistently included several social media sites: namely, YouTube, MySpace, Facebook, Hi5, Wikipedia and Orkut.com (2008). Despite their popular appeal, however, many of the Web 2.0 initiatives are still struggling to turn their popularity into financial success.

What is important to note is that when it comes to monetizing social media, there are no magic formulas. However, as explained above, the interactive nature of social media, combined with consumers' participation in the creation and dissemination of information, make viral marketing a viable candidate to fulfill the promise of a Web 2.0 of opportunities. In contrast to impersonal advertising methods that consumers do not trust and find intrusive, viral marketing through social media has the potential to be a personal, personable, participatory and trustworthy. source of information. Nonetheless, this should not be taken for granted that any and all viral marketing efforts in social media would be successful.

Extant literature suggests that there are certain prerequisites to a successful implementation of a viral marketing campaign in social media. First, as Webb (2007) suggests, because the company is going to have to rely on consumers to push the message, the message (and the product) should be worth pushing. Second, as consumers grow more suspicious of traditional advertising methods, marketers engaging in viral marketing in social media should pay the utmost attention to keeping viral marketing free from centralized interference that can damage its credibility. For example, Coplan (2007) notes that to remain credible, consumer marketers should be "honest about their opinions good and bad, open about their affiliation – and unpaid" (p. 26). This second prerequisite of success in social media marketing is closely related to the third one: In the world of consumer marketers, companies should learn to "cede control to customers" (cited in Poynter, 2008, p. 12). Partially, this means that viral marketing may be mixed with negative word of mouth and backlash (Gillin, 2007; Giuliana, 2005). At the same time, both positive and negative word of mouth should be considered as an opportunity to engage in a conversation with customers. For example, recently Cadbury PLC decided to relaunch Wispa (a chocolate bar discontinued in 2003) as a response to demands from 14,000 Facebook members (Poynter, 2008). Finally, as evidenced by the recent negative public reaction to the inadequate privacy protection on Facebook, marketers should be aware of the relatively intimate nature of social network sites.

KEY TERMS AND DEFINITIONS

Content Variability: *Content variability* refers to the notion that new media objects can exist in an infinite number of variations. This characteristic of new media is the result of the digital coding of content and consequently the modular nature of information.

Data Mining: Data mining is a technologically driven process of using algorithms to analyze data from multiple perspectives and extract meaningful patterns that can be used to predict future users behavior The market basket analysis system that Amazon.com uses to recommend new products to its customers on the basis of their past purchases is a widely known example of how data mining can be utilized in marketing.

Interactive Media: *Interactive media* is a catch-all term that is used to describe the two-way flow of information between the content user and the content producer. In addition to enabling consumers to actively participate in the production of content, interactive media also allow for the collection of real time data, which can later be used for content customization.

Semantic Web: The *Semantic Web* refers to a set of design principles, specifications, and web technologies that enable networked software agents to understand, interpret and communicate with each other to perform sophisticated tasks on behalf of users.

Social Network Analysis: Social network analysis is a research methodology utilized in research to investigate the structure and patterns of the relationship between social agents. Examples of sources of relational data include: contacts, connections, and group ties which can be studied using quantitative methodologies.

Social Network Sites: Social network sites are web-based systems that enable end-users to create online profiles, form associations with other users, and view other individuals' profiles. Examples of social network sites include: Match.

com, MySpace, Facebook, Orkut, Hi5, Bebo and LinkedIn.

Viral Marketing: *Viral marketing* refers to a form of word of mouth marketing that relies on consumers relaying product information, a marketing message or a personal endorsement to other potential buyers.

Web 2.0: Introduced in 2004, during a conference brainstorming session between O'Reilly Media and MediaLive International, *Web 2.0* refers to the second generation of web-based content. Rather than merely pointing to technological changes in the infrastructure of the Internet, the concept of Web 2.0 underlines the notion that end-users can do much more than consume readily available content: The user of Web 2.0 also plays a key role in the creation and the dissemination of content. Popular examples include: video-sharing and photo-sharing sites, such as YouTube and Flickr; social network sites, such as Orkut, MySpace and Facebook; and Weblogs (blogs).

Chapter 8.5
Web Content Recommendation Methods Based on Reinforcement Learning

Nima Taghipour
Amirkabir University of Technology, Iran

Ahmad Kardan
Amirkabir University of Technology, Iran

ABSTRACT

Information overload is no longer news; the explosive growth of the Internet has made this issue increasingly serious for Web users. Recommender systems aim at directing users through this information space, toward the resources that best meet their needs and interests. In this chapter we introduce our novel machine learning perspective toward the web recommendation problem, based on reinforcement learning. Our recommendation method makes use of the web usage and content data to learn a predictive model of users' behavior on the web and exploits the learned model to make web page recommendations. Unlike other recommender systems, our system does not use the static patterns discovered from web usage data, instead it learns to make recommendations as the actions it performs in each situation. In the proposed method we combined the conceptual and usage information in order to gain a more general model of user behavior and improve the quality of web recommendations. A hybrid web recommendation method is proposed by making use of the conceptual relationships among web resources to derive a novel model of the problem, enriched with semantic knowledge about the usage behavior. The method is evaluated under different settings and it is shown how this method can improve the overall quality of recommendations.

INTRODUCTION

The amount of information available on-line is increasing rapidly with the explosive growth of the World Wide Web and the advent of e-Commerce. Although this surely provides users with more options, at the same time makes it more difficult to find the "relevant" or "interesting" information from this great pool of information. This problem is commonly known as *information overload*: The state of having too much information to make a decision or remain informed about a topic. To address the problems caused by information overload, recommender systems have been introduced (Resnick & Varian, 1997). These systems can be defined as the personalized information technologies used to predict a user evaluation of a particular item (Deshpande & Karypis, 2004) or more generally as systems that guide users toward interesting or useful objects in a large space of possible options (Burke, 2002).

Recommender systems have been used in various applications ranging from predicting the products a customer is likely to buy (Shany *et al.*, 2005), movies, music or news that might interest the user (Konstan *et al.*, 1998; Zhang & Seo, 2001) and web pages that the user is likely to seek (Cooley *et al.*, 1999; Fu *et al.*, 2000; Joachims *et al.*, 1997; Mobasher *et al.*, 2000a), which is also the focus of this chapter. Web page recommendation is considered a user modeling or web personalization task (Eirinaki *et al.*, 2004). One research area that has recently contributed greatly to this problem is web mining. Most of the systems developed in this field are based on web usage mining which is the process of applying data mining techniques to the discovery of usage patterns form web data (Srivastava *et al*., 2000). These systems are mainly concerned with analyzing web usage logs, discovering patterns from this data and making recommendations based on the extracted knowledge (Fu *et al.*, 2000; Mobasher *et al.*, 2000a; Shahabi *et al.*, 1997; Zhang & Seo, 2001). One important characteristic of these systems is that unlike traditional recommender systems, which mainly base their decisions on user ratings on different items or other explicit feedbacks provided by the user (Deshpande & Karypis, 2004; Herlocker *et al.*, 2000), these techniques discover user preferences from their implicit feedbacks, e.g. the web pages they have visited. More recently, systems that take advantage of domain knowledge, e.g. a combination of content, usage and even structure information of the web, have been introduced and shown superior results in the web page recommendation problem (Li & Zaiane, 2004; Mobasher *et al.*, 2000b; Nakagawa & Mobasher, 2003).

In this chapter we will introduce a different machine learning perspective toward the web recommendation problem, which we believe is suitable to the nature of the problem and has some intrinsic advantages over previous methods. Our recommendation method falls in the category of methods that aim at supporting user's short-term information needs on a single website by recommending web pages to the user based on their navigation, such as previous works presented in (Mobasher *et al.*, 2000a,b; Li & Zaiane, 2004; Nakagawa & Mobasher, 2003). The proposed recommendation method makes use of the web usage and content data to learn a predictive model of users' behavior on the web and exploits the learned model to make web page recommendations to the users (Taghipour *et al.*, 2007; Taghipour & Kardan, 2007; Taghipour & Kardan, 2008). We model the recommendation process as a Reinforcement Learning (RL) problem (Sutton & Barto, 1998) or more specifically a Q-Learning problem. For this purpose we have devised state and action definitions and rewarding policies, considering common concepts and techniques used in the web mining domain. Then we train the system using web usage logs available as the training set, by adapting a variation of Q-learning algorithm. Our recommendation method differs from the previous methods in which the purpose was to find explicit and static patterns or rules, e.g. association rules or clusters of similar sessions, from the data. Here the system learns to make recommendations, i.e. predictions of interesting web pages, as the actions to perform in each situation (state). The choice of reinforcement learning was due to several reasons: It provides a framework appropriate to the nature of web page recommendation problem, mainly due to the concept of delayed reward or temporal difference in RL. Also, due to the characteristics of this type of learning and the fact that we are not making decisions explicitly from the static patterns discovered from the data, it provides us with a system which can potentially be constantly in the learning process and hence does not need periodic updates and can adapt itself to changes in website structure and content and more importantly to the new trends in user behavior.

We begin by introducing our method for web recommendations from web usage data (Taghipour *et al.*, 2007), i.e. usage logs available at web servers. Although the mentioned technique has shown promising results in comparison to common techniques like collaborative filtering and association rules, an analysis of the system's performance, shows how this method still suffers from the problems commonly faced by other usage-based techniques, such as the inability to generalize the learnt usage-based model which might results various problems such as the low coverage of recommendations or the "new item" problem commonly faced in collaborative filtering recommendations (Burke, 2002). To address these problems and to enhance our solution furthermore, we make use of the conceptual relationships among web pages and derive a novel model of the problem, enriched with semantic knowledge about the usage behavior (Taghipour & Kardan, 2008). We use existing methods to derive a conceptual structure of the website (Godoy & Amandi, 2005). Then we come up with new definitions for our states, actions and rewarding functions which capture the semantic implications of users' browsing behavior. Our new hybrid, i.e. usage- and content-based, model for the web page recommendation problem shows the flexibility of the reinforcement learning framework for the recommendation problem and how it can be extended to incorporate other sources of information. We evaluate our method under different settings and show how this method can improve the overall quality of web recommendations.

BACKGROUND

Web Recommender Systems

Recommender systems have been developed using various approaches and can be categorized in various ways (Burke, 2002). From an architectural point of view, recommendation generation approaches fall into two main categories: memory-based and model-based (Breese *et al.*, 1998). Memory based approaches memorize all the previous historical data, e.g. ratings, and make use of this data in the recommendation generation phase. Therefore, these techniques are more prone to scalability issues. Model-based approaches, on the other hand, use the available data to learn a model for recommendation. In these systems the computationally expensive learning phase is performed offline and hence they generally tend to scale better than memory based systems. It should be noted that as more data becomes available, memory based systems generally adapt better to changes in user interests. While in model based techniques, models must either be incremental or be rebuilt periodically to reflect the new trends.

From an algorithmic point of view recommender systems can be categorized into four general categories (Burke, 2002): knowledge-based systems, content-filtering systems, collaborative filtering systems and hybrid systems. Knowledge-based recommender systems make use of explicit domain knowledge about the items (such as their position in a concept hierarchy of the domain the items belong to) or the users (such as their demographic characteristics) to generate recommendations (Burke, 2000). Most of these recommenders employ some kind of knowledge-based decision rules for recommendation. This type of recommendation is heavily dependant on knowledge engineering by system designers to construct a rule base in accordance to the specific characteristics of the domain. While the user profiles are generally obtained through explicit interactions with users, there have also been some attempts at exploiting machine learning techniques for automatically deriving decision rules that can be used for personalization, e.g. (Pazzani, 1999).

In Content-based filtering systems, the user profile represents a content model of items in which that user has previously shown interest (Pazzani & Bilsus, 2007). These systems are rooted in information retrieval and information filtering research. The content model for an item is represented by a set of features or attributes characterizing that item. The recommendation generation is usually comprised of comparing extracted features from new items with content model in the user profile and recommending items that have adequate similarity to the user profile.

Collaborative techniques (Resnick & Varian, 1997; Herlocker *et al.*, 2000) are the most successful and the most widely used techniques in recommender systems, e.g. (Deshpande & Karypis, 2004; Konstan *et al.,* 1998; Wasfi, 1999). In the simplest from, in this class of systems, users are requested to rate the items they know and then the target user will be recommended the items that people with similar tastes had liked in the past. Recently, Web mining and especially web usage mining techniques have been used widely in web recommender systems (Cooley *et al.*, 1999; Fu *et al.*, 2000; Mobasher *et al.*, 2000a; Mobasher *et al.*, 2000b). Common approach in these systems is to extract navigational patterns from usage data by data mining techniques such as association rules and clustering, and making recommendations based on the extracted patterns. These approaches differ fundamentally from our method in which no static pattern is extracted from data.

More recently, systems that take advantage of a combination of content, usage and even structural information of the websites have been introduced and shown superior results in the web page recommendation problem (Li & Zaiane, 2004; Mobasher *et al.*, 2000b; Nakagawa & Mobasher, 2003). In (Nakagawa & Mobasher, 2003) the degree of connectivity based on the link structure of the website is used to choose from different usage based recommendation techniques, showing that sequential and non-sequential techniques could each achieve better results in web pages with different degrees of connectivity. A new method for generating navigation models is presented in (Li & Zaiane, 2004) which exploits the usage, content and structure data of the website. This method introduces the concept of user's *missions* to represent users' concurrent information needs. These missions are identified by finding content-coherent pages that the user has visited. Website structure is also used both for enhancing the content-based mission identification and also for ranking the pages in recommendation lists. In another approach (Eirinaki *et al.*, 2004, 2003) the content of web pages is used to augment usage profiles with semantics, using a domain-ontology and then performing data mining on the augmented profiles. Most recently, concept hierarchies were incorporated in a novel recommendation method based on web usage mining and optimal sequence alignment to find similarities between user sessions in (Bose *et al.*, 2007).

Markov Decision Process and Reinforcement Learning

Reinforcement learning (Sutton & Barto, 1998) is primarily known in machine learning research as a framework in which agents learn to choose the optimal action in each situation or state they are in. The agent is supposed to be in a specific state s, in each step it performs some action and transits to another state. After each transition the agent receives a reward. The goal of the agent is to learn which actions to perform in each state to receive the greatest accumulative reward, in its path to the goal states. The set of actions chosen in each state is called the agent's policy. One variation of this method is Q-Learning in which the agent does not compute explicit values for each state and instead computes a value function *Q(s,a)* which indicates value of performing action *a* in state *s* (Sutton & Barto, 1998; Mitchell, 1997). Formally the value of *Q(s,a)* is the discounted sum of future rewards that will be obtained by doing action *a* in s and subsequently choosing optimal actions. In order to solve the problem with Q-Learning we need to make appropriate definitions for our states and actions, consider a reward function suiting the problem and devise a procedure to train the system using web logs available to us.

The learning process of the agent can be formalized as a Markov Decision Process (MDP). The MDP model of the Problem includes:

1. **Set of states *S***, which represents the different 'situations' that the agent can observe. Basically, a state *s in S* must define what is important for the agent to know in order to take a good action. For a given situation, the complete set of states is called the *state space*.
2. **Set of possible actions *A*,** that the agent can perform in a given state *s* (*s* ∈ S) and that will produce a transition into a next state *s'* ∈ S. As we mentioned, the selection of the particular action depends on the *policy* of the agent. We formally define the policy as a function that indicates for each state *s*, the action *a* ∈ A taken by the agent in that state. In general, it is assumed that the environment, with which the agent interacts, is non-deterministic, i.e., after executing an action, the agent can transit into many alternative states.
3. **Reward function *rew*(*s, a*)** which assigns a scalar value, also known as the *immediate reward*, to the performance of each action *a* ∈ A taken in state *s* ∈ S. For instance, if the agent takes an action that is satisfactory for the user, then the agent should be rewarded with a positive immediate reward. On the other hand, if the action is unsatisfactory, the agent should be punished through a negative reward. However, the agent cannot know the reward function exactly, because the reward is assigned to it through the environment. This function can play a very important role in an MDP problem.
4. **Transition function *T*(*s, a, s'*)** which gives the probability of making a transition from state *s* to state *s'* when the agent performs the action *a*. This function completely describes the non-deterministic nature of the agent's environment. Explicit use of this function can be absent in some versions of Q-Learning.

Reinforcement Learning in Recommender Systems

Reinforcement Learning (RL) has been previously used for recommendations in several applications. Web Watcher (Joachims *et al.*, 1997), exploits Q-Learning to guide users to their desired pages. Pages correspond to states and hyperlinks to actions, rewards are computed based on the similarity of the page content and user profile keywords. There are fundamental differences between Web Watcher and our approach, two of the most significant are: (a) our approach requires no explicit user interest profile in any form, and (b) unlike our method, Web Watcher makes no use of previous usage based data. In most other systems, reinforcement learning is used to reflect user feedback and update current state of recommendations. A general framework is presented in (Golovin and Rahm, 2004), which consists of a database of recommendations generated by various models and a learning module that updates the weight of each recommendation by user feedback. In (Srivihok & Sukonmanee, 2005) a travel recommendation agent is introduced which considers various attributes for trips and customers, computes each trip's value with a linear function and updates function coefficients after receiving each user feedback. RL is used for information filtering in (Zhang & Seo, 2001) which maintains a profile for each user containing keywords of interests and updates each word's weight according to the implicit and explicit feedbacks received from the user. In (Shany *et al.*, 2005) the recommendation problem is modeled as an MDP. The system's states correspond to user's previous purchases, rewards are based on the profit achieved by selling the items and the recommendations are made using the theory of MDP and their novel state-transition function. In a more recent work (Mahmood & Ricci, 2007) RL is used in the context of a conversational travel recommender system in order to learn optimal interaction strategies. They model the problem with a finite state-space based on variables like the interaction stage, user action and the result size of a query. The set of actions represent what the system chooses to perform in each state e.g. executing a query, suggesting modification. Finally RL is used to learn an optimal strategy, based on a user behavior model. To the best of our knowledge our method differs from previous work, as none of them used reinforcement learning to train a system in making web site recommendations merely from web usage data.

REINFORCEMENT LEARNING FOR USAGE-BASED WEB PAGE RECOMMENDATION

The specific problem which our system is supposed to solve, can be summarized as follows: the system has, as input data, the log file of users' past visits to the website, these log files are assumed to be in any standard log format, containing records each with a user ID, the sequence of pages the user visited during a session and typically the time of each page request. A user session is defined as a sequence of temporally compact accesses by a user. Since web servers do not typically log usernames, sessions are considered as accesses from the same IP address such that they satisfy some constraints, e.g. the duration of time elapsed between any two consecutive accesses in the session is within a pre-specified threshold (Cooley et. al, 1999).

A user enters our website and begins requesting web pages, like a typical browser mostly by following the hyperlinks on web pages. Considering the pages this user has requested so far, the system has to predict in what other pages the user is probably interested and recommend them to her. Table 1 illustrates a sample scenario. Predictions are considered successful if the user chooses to visit those pages in the remaining of that session, e.g. page *c* recommended in the first step in Table 1. Obviously the goal of the system would be to make the most successful recommendations.

Modeling Recommendations as a Q-Learning Problem

Using the Analogy of a Game

In order to better represent our approach toward the problem we try to use the notion of a game. In a typical scenario a web user visits pages sequentially from a web site, let's say the sequence a user *u* requested is composed of pages *a, b, c* and *d*. Each page the user requests can be considered a step or move in our game. After each step the user takes, it will be the system's turn to make a move. The system's purpose is to predict user's next move(s) with the knowledge of his previous moves. Whenever the user makes a move (requests a page), if the system has previously predicted the move, it will receive positive points and otherwise it will receive none or negative points. For example predicting a visit of page *d* after viewing pages *a* and *b* by the user in the above example yields in positive points for the system. The ultimate goal of the system would be to gather as much points

Table 1. A sample user session and system recommendations

Visited Page	a	b	c	d	e	f
Navigation Trail	a	ab	abc	abcd	abcde	abcdef
System Prediction	c	d	e	s	f	h

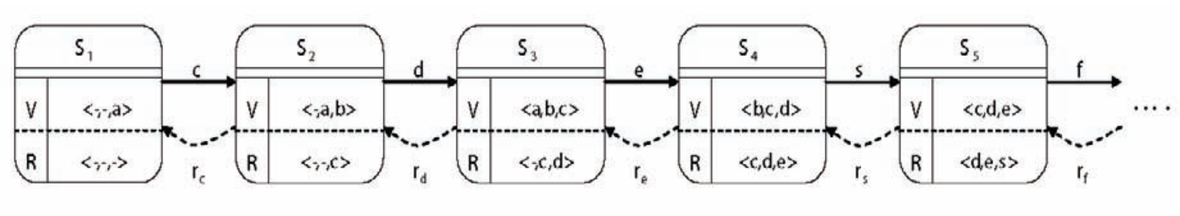
as possible during a game or actually during a user visit from the web site.

Some important issues can be inferred from this simple analogy: first of all, we can see the problem certainly has a stochastic nature and like most games, the next state cannot be computed deterministically from our current state and the action the system performs due to the fact that the user can choose from a great number of moves. This must be considered in our learning algorithm and our update rules for Q values; the second issue is what the system actions should be, as they are what we ultimately expect the system to perform. Actions will be prediction or recommendation of web pages by the system in each state. Regarding the information each state must contain, by considering our definition of actions, we can deduct that each state should at least show the history of pages visited by the user so far. This way we'll have the least information needed to make the recommendations. This analogy also determines the basics of rewarding function. In its simplest form it shall consider that an action should be rewarded positively if it recommends a page that will be visited in one of the consequent states, not necessarily the immediate next state. Of course, this would be an over simplification and in practice the reward would depend on various factors described in the coming sections. One last issue which is worth noting about the analogy is that this game cannot be categorized as a typical 2-player game in which opponents try to defeat each other, as in this game clearly the user has no intention to mislead the system and prevent the system from gathering points. It might be more suitable to consider the problem as a competition for different recommender systems to gather more points, than a 2-player game. Because of this intrinsic difference, we cannot use self-play, a typical technique used in training RL systems (Sutton & Barto, 1998) to train our system and we need the actual web usage data for training.

Modeling States and Actions

Considering the above observations we begin the definitions. We tend to keep our states as simple as possible, at least in order to keep their number manageable. Regarding the states, we can see keeping only the user trail can be insufficient. With that definition it won't be possible to reflect the effect of an action a performed in state s_i, in any consequent state s_{i+n} where $n>1$. This means the system would only learn actions that predict the immediate next page which is not the purpose of our system. Another issue we should take into account is the number of possible states: if we allow the states to contain any given sequence of page visits clearly we'll be potentially faced by an infinite number of states. What we chose to do was to limit the page visit sequences to a constant number. For this purpose we adopted the notion of N-Grams which is commonly applied in similar personalization systems based on web usage mining (Mobasher *et al.*, 2000a; Mobasher *et al.*, 2000b). In this model we put a sliding window of size w on user's page visits, resulting in states containing only the last w pages requested by the user. The assumption behind this model is that knowing only the last w page visits of the user, gives us enough information to predict his future page requests. The same problem rises when considering the recommended pages' sequence in

Figure 1. States and actions in the recommendation problem



the states, for which we take the same approach of considering *w'* last recommendations.

Regarding the actions, we chose simplicity. Each action is a single page recommendation in each state. Considering multiple page recommendations might have shown us the effect of the combination of recommended pages on the user, in the expense of making our state space and rewarding policy much more complicated.

Thus, we consider each state *s* at time *t* consisting of two sequences *V, R* indicating the sequence of visited and previously recommended pages respectively:

$$\begin{aligned} V_s &= < v_{t-w+1}, v_{t-w+2}, \ldots, v_t > \\ R_s &= < r_{t-w'+1}, r_{t-w'+2}, \ldots, r_t > \end{aligned} \quad (1)$$

Where v_{t-w+i} indicates the i^{th} visited page in the state and r_{t-w+i} indicates the i^{th} recommended page in the state *s*. The corresponding states and actions of the user session of Table 1 are presented in Figure 1, where straight arrows represent the actions performed in each state and the dashed arrows represent the reward received for performing each action.

Choosing a Reward Function

The basis of reinforcement learning lies in the rewards the agent receives, and how it updates state and action values. As with most stochastic environments, we should reward the actions performed in each state with respect to the consequent state resulted both from the agent's action and other factor's in the environment on which we might not have control. These consequent states are sometimes called the after-states (Sutton & Barto, 1998). Here this factor is the page the user actually chooses to visit. We certainly do not have a predetermined function *rew(s,a)* or even a state transition function $\delta(s, a)$ which gives us the next state according to current state s and performed action a.

It can be inferred that the rewards are dependent on the after state and more specifically on the intersection of previously recommended pages in each state and current page sequence of the state. Reward for each action would be a function of $V_{s'}$ and $R_{s'}$ where *s'* is our next state. One tricky issue worth considering is that though tempting, we should not base on rewards on $|V_s' \cap R_{s'}|$ since it will cause extra credit for a single correct move. Considering the above example a recommendation of page b in the first state shall be rewarded only in the transition to the second state where user goes to page b, while it will also be present in our recommendation list in the third state. To avoid this, we simply consider only the occurrence of the last visited page in state *s'*, in the recommended pages list to reward the action performed in the previous sate *s*. To complete our rewarding procedure we take into account common metrics used in web page recommender systems. One issue is considering when the page was predicted by the system and when the user actually visited the page. According to the goal of the system this might influence our rewarding. If we consider shortening user navigation as a sign of successful guidance of user to his required information, as is the most common case in recommender systems (Li & Zaiane, 2004; Mobasher *et al.,* 2000a) we should consider a greater reward for pages predicted sooner in the user's navigation path and vice versa. Another factor commonly considered in theses systems (Mobasher *et al.,* 2000a; Liu *et al.,* 2004; Fu *et al.,* 2000) is the time the user spends on a page, assuming the more time the user spends on a page the more interested he probably has been in that page. Taking this into account we should reward a successful page recommendation in accordance with the time the user spends on the page. The rewarding can be summarized as follows:

Algorithm 1. Usage Based Reward Function

1: **Assume** $\delta(s,a) = s'$

2: $K_{s'} = V_{s',w} \cap R_{s'} = v_{t+1} \cap R_{s'}$

3: **If** $K_{s'} \neq \emptyset$

4: **For each** *page k* **in** $K_{s'}$

5: *rew(s,a) += UBR(Dist(*$R_{s'}$*, k),Time(*v_{t+1}*))*

6: **End For**

7: **End If**

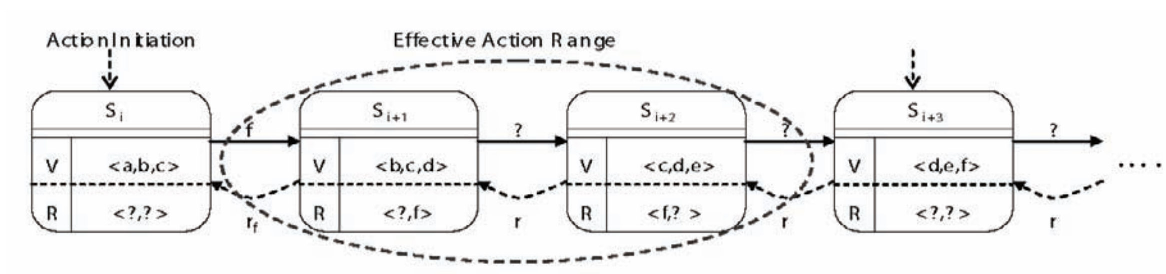
In line 1, $\delta(s,a) = s'$ shows that the transition of the system to the next state *s'* after performing *a* in state *s*. $K_{s'}$ represents the set of correct recommendations in each step and *rew(s,a)* is the reward of performing action *a* in state *s*. *Dist(*$R_{s'}$*,k)* is the distance of page *k* from the end of the recommended pages list in state *s'* and *Time(*v_{t+1}*)* indicates the time user has spent on the last page of the state. Here, *UBR* is the Usage-Based Reward function, combining these values to calculate the reward function *rew(s,a)*. We chose a simple linear combination of these values as Equation (2):

$$UBR(Dist, Time) = \alpha \times Dist + \beta \times Time \qquad (2)$$

Where $\alpha + \beta = 1$ and both α and β include a normalizing factor according to the maximum values dist and time can take.

The last modification we experimented was changing our reward function. We noticed as we put a sliding window on our sequence of previously recommended pages, practically we had limited the effect of each action to *w'* next states as can be seen in Figure 2. As can be seen in the example presented in this figure, a correct recommendation of page *f* in state s_i will not be rewarded in state s_{i+3} when using a window of size 2 on the *R* sequence (*w'=2)*. After training the system using this definition, the system was mostly successful in recommending pages visited around *w'* steps ahead. Although this might be quite acceptable while choosing an appropriate value for *w'*, it tends to limit system's prediction ability as large numbers of *w'* make our state space enormous. To overcome this problem, we devised a rather simple modification in our reward function: what we needed was to reward recommendation of a page if it is likely to be visited an unknown number of states ahead. Fortunately our definition of states and actions gives us just the information we need and this information is stored in *Q* values of each state. The basic idea is that when an action/recommendation is appropriate in state s_i, indicating the recommended page is likely to occur in the following states, it should also be considered appropriate in state s_{i-1} and the actions in that state that frequently lead to s_i. Following this recursive procedure we can propagate the value of performing a specific action beyond the limits imposed by *w'*. This change is easily reflected in our learning system by considering value of *Q(s',a)* in computation of *rew(s,a)* with a coefficient like γ. It should be taken into account that the effect of this modification in our reward

Figure 2. An example of limited action effectiveness due to the size of the recommendation window



function must certainly be limited as in its most extreme case where we only take this next *Q* value into account we're practically encouraging recommendation of pages that tend to occur mostly in the end of user sessions.

Having put all the pieces of the model together, we can get an initial idea why reinforcement learning might be a good candidate for the recommendation problem: it does not rely on any previous assumptions regarding the probability distribution of visiting a page after having visited a sequence of pages, which makes it general enough for diverse usage patterns as this distribution can take different shapes for different sequences. The nature of this problem matches perfectly with the notion of delayed reward or what is commonly known as temporal difference: the value of performing an action/recommendation might not be revealed to us in the immediate next state and sequence of actions might have led to a successful recommendation for which we must credit rewards. What the system learns is directly what it should perform, though it is possible to extract rules from the learned policy model, its decisions are not based on explicitly extracted rules or patterns from the data. One issue commonly faced in systems based on patterns extracted from training data is the need to periodically update these patterns in order to make sure they still reflect the trends residing in user behavior or the changes of the site structure or content. With reinforcement learning the system is intrinsically learning even when performing in real world, as the recommendations are the actions the system performs, and it is commonplace for the learning procedure to take place during the interaction of system with its environment.

Training the System

We chose Q-Learning as our learning algorithm. This method is primarily concerned with estimating an evaluation of performing specific actions in each state, known as Q-values. Each *Q(s,a)* indicates an estimate of the accumulative reward achievable, by performing action *a* in state *s* and performing the action *a'* with highest *Q(s',a')* in each future state *s'*. In this setting we are not concerned with evaluating each state in the sense of the accumulative rewards reachable from this state, which with respect to our system's goal can be useful only if we can estimate the probability of visiting the following states by performing each action. On the other hand Q-Learning provides us with a structure that can be used directly in the recommendation problem, as recommendations in fact are the actions and the value of each recommendation/action shows an estimation of how successful that prediction can be. Another decision is the update rule for Q values.

Because of the non-deterministic nature of this problem we use the following update rule (Sutton & Barto, 1998):

$$Q_n(s,a) = (1-\alpha_n)Q_{n-1}(s,a) + \alpha_n[r(s,a) + \gamma \max_{a'} Q_{n-1}(\delta(s,a),a')] \quad (3)$$

Figure 3. Algorithm 2: Training procedure

- Initial values of *Q(s,a)* for each pair *s,a* are set to zero
- Repeat until convergence
  - A random episode is chosen from the set of training episodes.
  - *s* is set to the first step/state of the episode.
  - For each step of the episode do
    - Choose an action *a* of this state using the ε-greedy policy.
    - Perform action a observe the next state and compute *rew(s,a)* as described before.
    - Update value of *Q(s,a)* with the above equation.
    - $s \leftarrow s'$.

With

$$\alpha_n = \frac{1}{1 + visits_n(s,a)} \tag{4}$$

Where $Q_n(s,a)$ is the Q-Value of performing *a* in state *s* after *n* iterations, and $visits_n(s,a)$ indicates the total number of times this state-action pair, i.e. *(s,a)*, has been visited up to and including the n^{th} iteration. This rule takes into account the fact that doing the same action can yield different rewards each time it is performed in the same state. The decreasing value of α_n causes these values to gradually converge and decreases the impact of changing reward values as the training continues.

What remains about the training phase is how we actually train the system using web usage logs available. As mentioned before these logs consist of previous user sessions in the web site. Considering the analogy of the game they can be considered as a set of opponent's previous games and the moves he tends to make. We are actually provided with a set of actual episodes occurred in the environment, of course with the difference that no recommendations were actually made during these episodes. The training process can be summarized as Figure 3. Algorithm 2:

One important issue in the training procedure is the method used for action selection. One obvious strategy would be for the agent in each state *s* to select the action *a* that maximizes *Q(s,a)* hereby exploiting its current approximation. However, with this greedy strategy there's the risk of over-committing to actions that are found during early training to have high Q values, while failing to explore other actions that might have even higher values (Mitchell, 1997). For this reason, it is common in Q learning to use a probabilistic approach to selecting actions. A simple alternative is to behave greedily most of the time, but with small probability ε, instead select an action at random. Methods using this near-greedy action selection rule are called ε-greedy methods (Sutton & Barto, 1998).

The choice of ε-greedy action selection is quite important for this specific problem as the exploration especially in the beginning phases of training, is vital. The Q values will converge if each episode, or more precisely each state-action pair is visited infinitely. In our implementation of the problem convergence was reached after a few thousand (between 3000 and 5000) visits of each episode. This definition of the learning algorithm completely follows a *TD(0)* off-policy learning procedure (Sutton & Barto, 1998), as we take an estimation of future reward accessible from each state after performing each action by considering the maximum *Q* value in the next state.

EXPERIMENTAL EVALUATION OF THE USAGE BASED APPROACH

We evaluated system performance in the different settings described above. We used simulated log files generated by a web traffic simulator to tune our rewarding functions. The log files were simulated for a website containing 700 web pages. We pruned user sessions with a length smaller than 5 and were provided with 16000 user sessions with average length of eight. As our evaluation data set we used the web logs of the Depaul University website, one of the few publicly available and widely used datasets, made available by the author of (Mobasher *et al.*, 2000a). This dataset is pre-processed and contains 13745 user sessions in their visits on 687 pages. These sessions have an average length around 6. The website structure is categorized as a dense one with high connectivity between web pages according to (Nakagawa & Mobasher, 2003). 70% of the data set was used as the training set and the remaining was used to test the system. For our evaluation we presented each user session to the system, and recorded the recommendations it made after seeing each page the user had visited. The system was allowed to make r recommendations in each step with $r<10$ and $r < \sqrt{O_v}$ where O_v is the number of outgoing links of the last page v visited by the user. This limitation on number of recommendations is adopted from (Li & Zaiane, 2004). The recommendation set in each state is composed by selecting the *top-r* actions of the sates with the highest Q-values, again by a variation of the ε-greedy action selection method.

Evaluation Metrics

To evaluate the recommendations we use the metrics presented in (Li & Zaiane, 2004) because of the similarity of the settings in both systems and the fact that we believe these co-dependent metrics can reveal the true performance of the system more clearly than simpler metrics. Recommendation Accuracy and Coverage are two metrics quite similar to the precision and recall metrics commonly used in information retrieval literature.

Recommendation accuracy measures the ratio of correct recommendations among all recommendations, where correct recommendations are the ones that appear in the remaining of the user session. If we have M sessions in our test log, for each visit session m after considering each page p, the system generates a set of recommendations *Rec(p)*. To compute the accuracy, *Rec(p)* is compared with the rest of the session *Tail(p)* as Equation (5). This way any correct recommendation is evaluated exactly once.

$$Accuracy = \frac{\sum_m \frac{\left|\bigcup_p (Tail(p) \cap \mathrm{Re}\,c(p))\right|}{\left|\bigcup_p \mathrm{Re}\,c(p)\right|}}{M} \tag{5}$$

Recommendation coverage on the other hand shows the ratio of the pages in the user session that the system is able to predict before the user visits them:

$$Coverage = \frac{\sum_m \frac{\left|\bigcup_p (Tail(p) \cap \mathrm{Re}\,c(p))\right|}{\left|\bigcup_p Tail(p)\right|}}{M} \tag{6}$$

As is the case with precision and recall, these metrics can be useful indicators of the system performance only when used in accordance to each other and lose their credibility when used individually. As an example, consider a system that recommends all the pages in each step, this system will gain 100% coverage, of course in the price of very low accuracy.

Another metric used for evaluation is called the shortcut gain which measures how many page-visits users can save if they follow the recommendations. The shortened session is derived by eliminating the intermediate pages in the session that the user could escape visiting, by following the recommendations. A visit time threshold is used on the page visits to decide which pages are auxiliary pages as proposed by Li and Zaiane (2004). If we call the shortened session *m'*, the shortcut gain for each session is measured as follows:

$$ShortcutGain = \frac{\frac{|m| - |m'|}{|m|}}{M} \tag{7}$$

Evaluation Results

In the first set of experiments we tested the effect of different decisions regarding state definition, rewarding function, and the learning algorithm on the system behavior. Afterwards we compared the system performance to the other common techniques used in recommendation systems.

Sensitivity to Active Window Size on User Navigation Trail

In our state definition, we used the notion of N-Grams by putting a sliding window on user navigation paths. The implication of using a sliding window of size w is that we base the prediction of user future visits on his w past visits. The choice of this sliding window size can affect the system in several ways. A large sliding window seems to provide the system a longer memory while on the other hand causing a larger state space with sequences that occur less frequently in the usage logs. We trained our system with different window sizes on user trail and evaluated its performance as seen in Figure 4. In these experiments we used a fixed window size of 3 on recommendation history.

As our experiments show the best results are achieved when using a window of size 3. It can be inferred form this diagram that a window of size 1 which considers only the user's last page visit does not hold enough information in memory to make the recommendation, the accuracy of recommendations improve with increasing the window size and the best results are achieved with a window size of 3. Using a window size larger than 3 results in weaker performance (only shown up to *w=4* in Figure 4 for the sake of readability), it seems to be due to the fact that, as mentioned above, in these models, states contain sequences of page visits that occur less frequently in web usage logs, causing the system to make decisions based on weaker evidence. In our evaluation of the short cut gain there was a slight difference when using different window sizes.

Sensitivity to Active Window Size on Recommendations

In the next step we performed similar experiments, this time using a constant sliding window of size 3 on user trail and changing size of active window on recommendations history. As this window size was increased, rather interesting results was achieved as shown in Figure 5.

In evaluating system accuracy, we observed improvement up to a window of size 3, after that increasing the window size caused no improvement while resulting in larger number of states. This increase in the number of states is more intense than when the window size on user trail was increased. This is manly due to the fact that the system is exploring and makes any combination of recommendations to learn the good ones. The model consisting of this great number of states is in no way efficient, as in our experiments on the test data only 25% of these states were actually visited. In the sense of shortcut gain the system achieved, it was observed that shortcut gain increased almost constantly with increase in window size, which seems a natural consequence as described in section "Reinforcement learning for usage-based web page recommendation".

Figure 4. System performance with various user visit windows sizes (w)

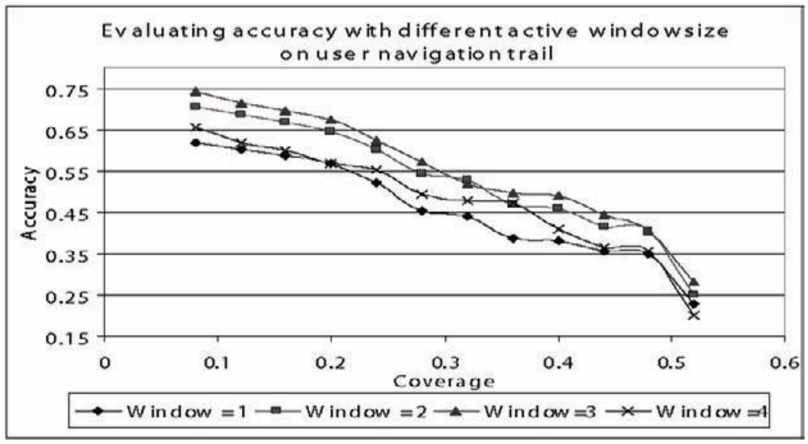


Figure 5. System performance with different active recommendation windows (w')

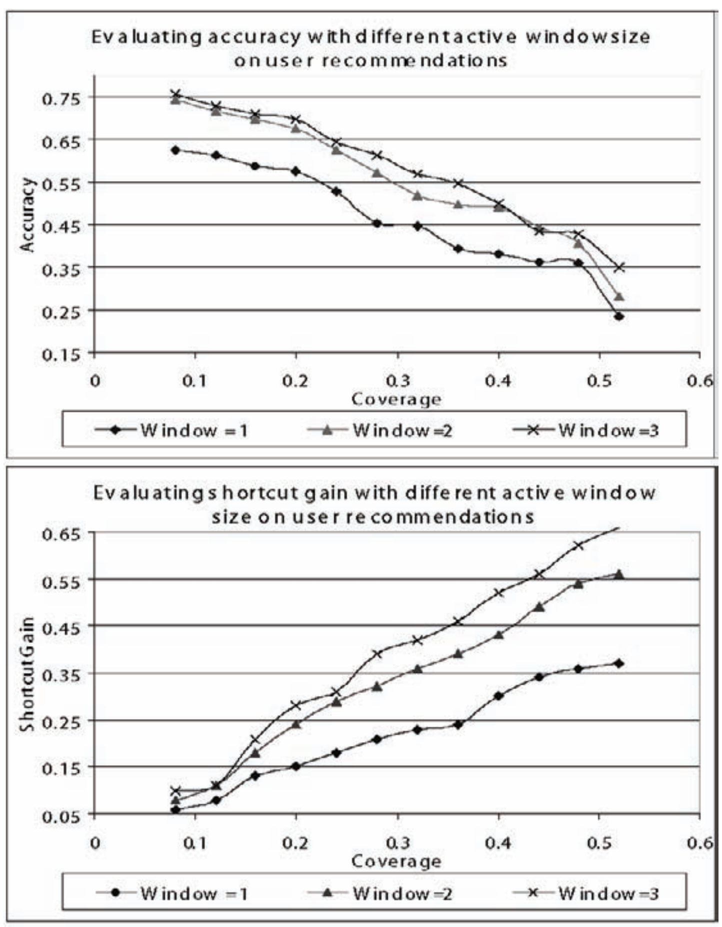


Evaluating Different Reward Functions

Next we changed the effect of parameters constituting our reward function. First we began by not considering the *Dist* parameter, described in section "Reinforcement learning for usage-based web page recommendation", in our rewards. We gradually increased it's coefficient in steps of 5% and recorded the results as shown in Table 2. These results show that increasing the impact of this parameter in our rewards up to 15% of total reward can result both in higher accuracy and higher shortcut gain. Using values greater than 15% has a slight negative effect on accuracy with a slight positive effect on shortcut gain and keeping it almost constant. This seems a natural consequence since although we're paying more attention to pages that tend to appear later in the user sessions, the system's vision into the future is bounded by the size of window on recommendations. This limited vision also explains why our accuracy is not decreasing as expected.

The next set of experiments tested system performance with the reward function that considers *next state Q-value* of each action in rewarding the action performed in the previous state, as described in section "Reinforcement learning for usage-based web page recommendation". We began by increasing the coefficient of this factor (γ) in the reward function the same way we did for the *Dist* parameter. In the beginning increasing this value, lead to higher accuracy and shortcut gains. After reaching an upper bound, the accuracy began to drop. In these settings, recommendations with higher values were those targeted toward the pages that occurred more frequently in the end of user sessions. These recommended pages, if recommended correctly, were only successful in predicting the last few pages in the user sessions. As expected, shortcut gain increased steadily with increase in this value up to a point where the recommendations became so inaccurate that rarely happened anywhere in the user sessions. More detailed evaluation results, which are not presented here due to space constraints, can be found in (Taghpour *et al.*, 2007).

A Comparison with other Methods

Finally we observed our system performance in comparison with two other methods: (a) association rules, as one approach based on of the usage-pattern and one of the most common approaches in web mining based recommender systems (Mobasher *et al.*, 2000a,b); and collaborative filtering which is commonly known as one of the most successful approaches for recommendations. We chose item-based collaborative filtering with

Table 2. System performance with varying α in the reward function. (AC=Accuracy, SG=Shortcut Gain)

Coverage	**Performance**									
	$\alpha = 0.1$		$\alpha = 0.15$		$\alpha = 0.20$		$\alpha = 0.25$		$\alpha = 0.30$	
	AC	SG	AC	SG	AC	SG	AC	SG	AC	SG
10	.75	.15	.78	.17	.76	.17	.73	.18	.69	.18
15	.71	.28	.73	.33	.72	.35	.69	.34	.65	.35
20	.69	.37	.68	.40	.67	.41	.67	.41	.61	.41
25	.65	.40	.66	.44	.65	.44	.61	.46	.58	.46
30	.55	.43	.57	.50	.54	.53	.52	.54	.49	.57
40	.48	.48	.50	.54	.45	.57	.40	.58	.36	.57
50	.36	.51	.39	.57	.33	.58	.29	.58	.27	.59

probabilistic similarity measure (Deshpande & Karypis, 2004), as a baseline for comparison because of the promising results it had shown. It should be noted that these techniques have already shown significantly superior results compared to common sense methods such as recommending most popular items (pages) of a collection. In Figure 6 the performance of these systems in the sense of their accuracy and shortcut gain in different coverage values can be seen. The statistical significance of any differences in performance between two methods was evaluated using two-tailed paired t-tests (Mitchell, 1997).

At lower coverage values we can see although our system still has superior results especially over association rules, accuracy and shortcut gain values are rather close. As the coverage increases, naturally accuracy decreases in all systems, but our system gains much better results than the other two systems. It can be seen the rate in which accuracy decreases in our system is lower than other two systems; at lower coverage values where the systems made their most promising recommendations (those with higher values), pages recommended were mostly the next immediate page and as can be seen had an acceptable accuracy. At lower coverage rates, where recommendations with lower values had to be made our system began recommending pages occurring in the session some steps ahead, while the other approaches also achieved greater shortcut gains, as the results show their lower valued recommendations were not as accurate and their performance declined more intensely. Regardless of the size of the difference at different coverage values, all the differences in Accuracy and Shortcut Gain between our proposed method and the baseline approaches are statistically significant (p<0.001 on the t-test).

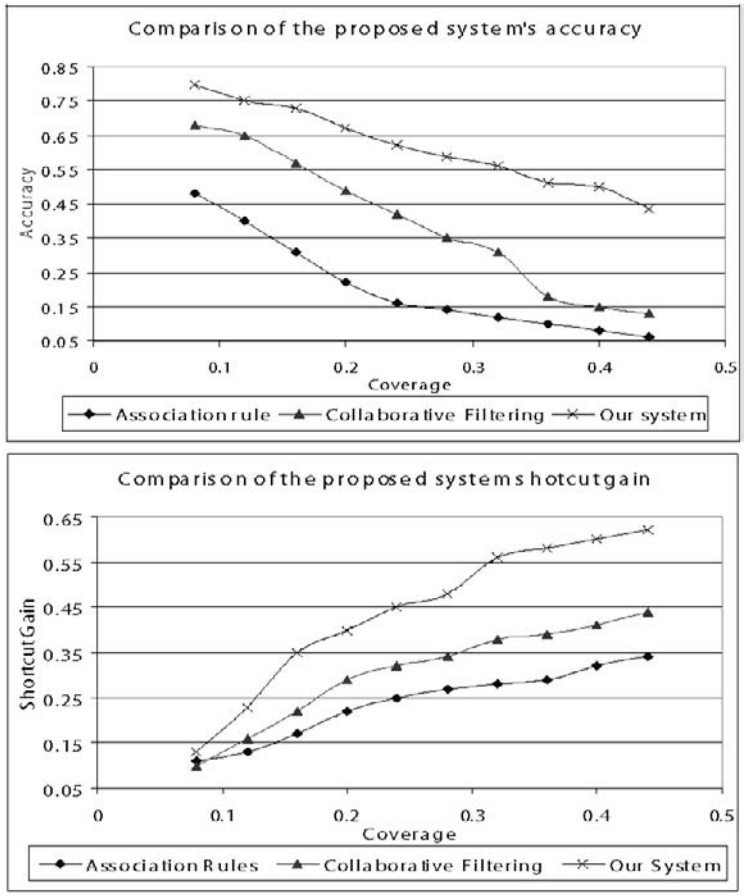
INCORPORATING CONTENT FOR HYBRID WEB RECOMMENDATIONS

In this section we exploit the idea of combining content and usage information to enhance the reinforcement learning solution, we had devised for web page recommendations based on web usage data. Although the mentioned technique showed promising results in comparison to common techniques like collaborative filtering and association rules, an analysis of the system's performance, reveals that this method still suffers from the problems commonly faced by other usage-based techniques. To address these problems, we made use of the conceptual relationships among web pages and derived a new model of the problem, enriched with semantic knowledge about the usage behavior. We used existing methods to derive a conceptual structure of the website. Then we came up with new definitions for our states, actions and rewarding functions which capture the semantic implications of users browsing behavior.

Observations on Performance of the Usage-Based Approach

In our evaluation of the system, we noticed that although we were faced with a rather large number of states, there were cases where the state resulted from the sequence of pages visited by the user had actually never occurred in the training phase. Although not the case here, this problem can be also due to the infamous "new item" problem commonly faced in collaborative filtering (Burke, 2002; Mobasher *et al.*, 2000b) when new pages are added to the website. In situations like these the system was unable to make any decisions regarding the pages to recommend to the users. Moreover, the overall coverage of the system on the website, i.e. percentage of the pages that

Figure 6. Comparing our system's performance with two other common methods



were recommended at least once, was rather low (55.06%). Another issue worth considering is the fact that the mere presence of a state in our state space cannot guarantee a high quality recommendation, to be more accurate it can be said that even a high Q-value cannot guarantee a high quality recommendation by itself. Simply put, when a pattern has few occurrences in the training data it cannot be a strong basis for decision making, a problem addressed in other methods by introducing metrics like support threshold in association rules (Mobasher *et al.*, 2000b). Similarly in our case a high Q-value, like a high confidence for an association rule, cannot be trusted unless it has strong supporting evidence in the data. In summary, there are cases when historical usage data provides no evidence or evidence that's not strong enough to make a rational decision about user's need or behavior.

This is a problem common in recommender systems that have usage data as their only source of information. Note that in the described setting, pages stored in the *V* sequence of each state *S* are treated as items for which the only information available is their id. The system relies solely on usage data and thus is unable to make any generalization. One common solution to this problem is to incorporate some semantic knowledge about the items being recommended, into the system. In the next section we describe our approach for adopting this idea.

Incorporating Concept Hierarchies in the Recommendation Model

One successful approach used to enhance web usage mining, is exploiting content information to transform the raw log files into more meaningful semantic logs (Bose *et al.*, 2006; Eirinaki *et al.*, 2004) and then applying data mining techniques on them. In a typical scenario pages are mapped to higher level concepts e.g. catalogue page, product page, etc and a user session consisting of sequential pages will be transformed to a sequence of concepts followed by the user. Consequently, generalized patterns are extracted from these semantically enhanced log files which can then be used for personalization.

We decided to exploit the same techniques in our system to improve our state and action model. In order to make our solution both general and applicable, we avoided using an ad-hoc concept hierarchy for this purpose. Instead we chose to exploit hierarchical and conceptual document clustering which can provide us with semantic relationships between pages without the need of a specifically devised ontology, concept hierarchy or manual assignment of concepts to pages. An important factor in our selection was the ability of the method to perform incremental document clustering, since we prefer to come up with a solution that is able to cope with the changes in the web site content and structure. In order to map pages to higher level concepts, we applied the DCC clustering algorithm (Godoy & Amandi, 2005) on the web pages. It is an incremental hierarchical clustering algorithm which is originally devised to infer user needs and falls in the category of conceptual clustering algorithms as it assigns labels to each cluster of documents. In this method each document would be assigned to a single class in the hierarchy. This method has shown promising results in the domain of user profiling based on the web pages visited by the user from web corpuses. We use this method to organize our documents similar to the manner in which they're assigned to nodes of a concept hierarchy. It should be noted that the output of other more sophisticated approaches like the one proposed in (Eirinaki *et al.*, 2004) for generating C-Logs could also be used for this purpose without affecting our general RL model.

Conceptual States and Actions

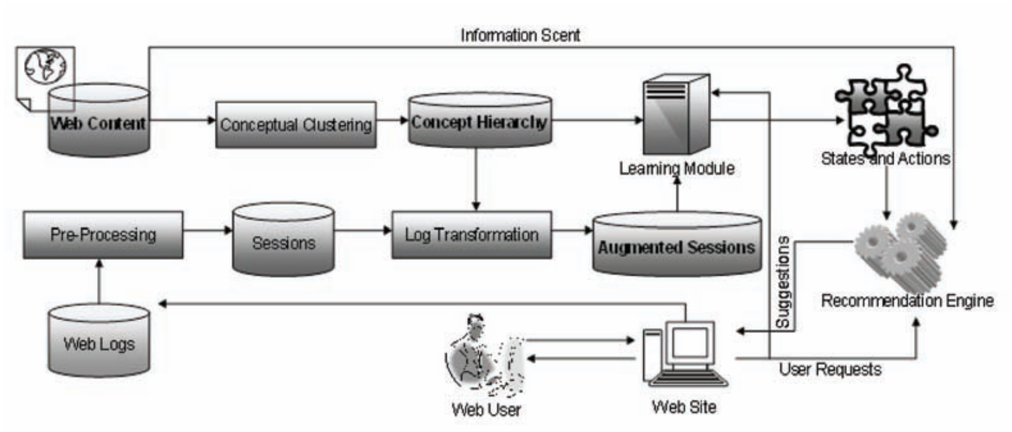
After clustering the web pages in the hierarchy, our state and action definition change as follows. Instead of keeping a sequence V of individual page visits by the user, each state would consist of a sequence of concepts visited by the user. Considering a mapping like $C : P \rightarrow H$ which transforms each page *p* in the set of pages *P* to the corresponding concept *c* in the concept hierarchy *H*, the states *s* in each time step *t* would now be defined as:

$$\begin{aligned} V_s &= < C(v_{t-w+1}), C(v_{t-w+2}), \ldots, C(v_t) > \\ R_s &= < C(r_{t-w'+1}), C(r_{t-w'+2}), \ldots, C(r_t) > \end{aligned} \qquad (8)$$

Also, the actions are now recommendation of pages that belong to a specific concept. In order to do so we need a module to find the node each page belongs to in the concept hierarchy and transform each usage log to a sequence of concepts in the training phase. The other aspects of the system like the reward function and the learning process would remain the same, e.g. an action a recommending a concept c is rewarded if the user visits a page belonging to concept c later in his browsing session.

This definition results in a much smaller state-action space as now the state space size is dependant on the number of distinct page clusters instead of the number of distinct web pages in the website. Consequently, the learning process will become more efficient and the system will have a more general model of users' browsing behavior on the site. With this generalized definition, the chance of confronting an unseen state will be much less

Figure 7. Architecture of the Hybrid Recommender System



and actually minimized as our evaluation results show. We'll no longer make decisions based on weak usage patterns as now the states represent a generalized view of many single visit sequences, and the average number of times a state is visited in user sessions is now 10.2 times the average visit of states in the usage-based setting. A general view of the system is depicted in Figure 7.

In the test phase, the user's raw session will be converted to a semantic session, the corresponding state will be found and the page cluster with the highest value is identified. When a concept is chosen as the action, the next step would be to recommend pages from the chosen cluster(s). Initially we chose to recommend the pages with a probability corresponding to their similarity to the cluster mean vector. This new definition of actions enables the system to cover a wider range of pages to be recommended as our evaluations show, and also the potential ability of avoiding the "new item" problem as any new page will be categorized in the appropriate cluster and have a fair chance of being recommended.

A Content-Based Reward Function

We can also make use of the content information of web pages and their relative positioning in the concept hierarchy in our reward function. The new rewarding function takes the content similarity of the recommended and visited pages into account. The basic idea behind this method is to reward recommendation of a concept c in s_i which might not be visited in s_{i+1} but is semantically similar to the visited page v, or more precisely, to the concept that v belongs to. The new reward function would be basically same as the one presented in Algorithm 1, the only difference is that instead of using *rew(s,a)* in step 5, now the reward would be computed by the new function *HybridRew(s,a)* shown in Equation 9.

$$HybridRew(s,a)= UBR(Dist(R_{s'}, a),Time(v_{t+1}))\times CBR(a, v_{t+1}) \quad (9)$$

Here *CBR* represents the content-based reward of an action and *UBR* is the usage based reward which is our previous reward function used in step 5 of Algorithm 1.

In order to compute the content based reward we use the method for computing similarity of nodes in a concept hierarchy proposed in (Bose *et al.*, 2006). In this method, first a probability $p(c)$ is assigned to each concept node c which is proportional to the frequency of pages belonging to this node and its descendants in user sessions. The information content of each node is then defined as:

$$I(c) = -\log p(c) \tag{10}$$

Then a set *LCA* is found which contain the Least Common Ancestors, those occurring at the deepest level, of the pair of concept nodes. And the similarity score between those are computed as:

$$Sim(c_1, c_2) = \max_{a \in LCA}\{I(a)\} \tag{11}$$

The *CBR* for each recommended page *a* will be equal to the similarity score:

$$CBR(a, v_{t+1}) = Sim(C(a), C(v_{t+1})) \tag{12}$$

This method seems specifically appropriate for the off-line training phase where recommendations are evaluated using the web usage logs. In this phase actions are predictions of the user's next visit and web pages are not recommended to the user in the on-line browsing sessions. As a result actual user reactions towards pages cannot be assessed and the assumption is made that users interest toward a recommendation can be estimated as function of conceptual similarity between the recommended and visited pages.

The situation is a bit different when the system provides on-line recommendations to the user. Here the usage-based reward is given more weight than the reward based on content similarity. This is based on the idea that the overall judgment of users can be trusted more than the content similarity of pages, since satisfying user information need is the ultimate goal of personalization.

Selection of Pages in a Concept

Based on the actions, we can decide which concept the user is interested in. In order to make recommendations, we should select a page belonging to that concept, which is not a trivial task especially when we're faced with large clusters of pages. Our initial solution was to rank pages with respect to their distance from cluster center. Our experiments show that this method does not yield in accurate recommendations. In order to enhance our method we exploited the content information of web pages and the hyperlinks that the users have followed in each state. The text around the chosen hyperlinks in each page has been used as an indicator of user information need in user modeling, based on the information scent model (Chi *et al.*, 2001). We also employ the information scent to compute a vector representing user information need in each state. The method we used is basically similar to (Chi *et al.*, 2001), using the text around the hyperlink, the title of the out going page etc., with the exception that we assign more weight to the hyperlinks followed later in each state. After computing this vector we use the cosine based similarity to find the most relevant pages in each selected page cluster for recommendation.

Overall, we experimented with three different methods for ranking pages for selection from a given concept *c'* (pages with lower ranks have higher probability of being selected):

1. Ranking based on the distance of a page from Cluster Mean (*HCM*): The basic idea here is that pages which are closer to the cluster mean vector are more relevant to the given concept and hence might be more relevant to a user interested in that concept. Considering $\boldsymbol{W}_{c'}$ as the mean content vector of concept *c'*, and the vector $\boldsymbol{W}_i$, representing each web page p_i ($p_i \in P$ and $C(p_i) = c'$), the selection rank of each p_i, shown by $SelRank_{CM}(p_i)$, would be computed according to (14). This rank is in reverse relation with the distance of $\boldsymbol{W}_i$ from $\boldsymbol{W}_{c'}$. In these experiments we computed the distance using the cosine of these two vectors.

$$SelRank_{CM}(p_i) \le SelRank_{CM}(p_j) \Leftrightarrow Dist(W_{C'}, W_i) \le Dist(W_{C'}, W_j) \tag{13}$$

2. Ranking based on the occurrence frequency of a page (*HFreq*): this method is primarily based on historical usage data. The rationale is that pages which are more frequently visited by users might more popular in the collection of pages related to a concepts and therefore more probable to be sought by the target user. Considering $Frq(p_i)$ as the occurrence frequency of each p_i ($p_i \in P$ and $C(p_i) = c'$), the selection rank of each p_i, shown by $SelRank_{Freq}(p_i)$, would be in reverse relation with the distance this frequency.

$$SelRank_{Freq}(p_i) \leq SelRank_{Freq}(p_j) \Leftrightarrow Frq(p_i) \geq Frq(p_j) \tag{14}$$

3. Ranking based on the Information Scent model (*HIS*): in this approach, based on the information foraging theory, it is assumed that the information need of the user van be estimated by the proximal cues that the user follows in his navigation on the web. Here, pages are ranked in accordance to their similarity to the vector derived by the information scent model from the sequence of pages visited in each state. Considering $\boldsymbol{W}_{IS}$ as the information scent vector, and the vector $\boldsymbol{W}_i$, representing each web page p_i ($p_i \in P$ and $C(p_i) = c'$), the selection rank of each p_i, shown by $SelRank_{IS}(p_i)$, would be computed according to (15). This rank is in accordance with the similarity of $\boldsymbol{W}_i$ to $\boldsymbol{W}_{IS}$. In our experiments, the similarity of two vectors was computed using the cosine-based similarity function commonly used in information retrieval.

$$SelRank_{IS}(p_i) \leq SelRank_{IS}(p_j) \Leftrightarrow Sim(W_{IS}, W_i) \geq Sim(W_{IS}, W_j) \tag{15}$$

EXPERIMENTAL EVALUATION OF THE HYBRID RECOMMENDATION METHOD

Evaluation Metrics

We pointed out the main weaknesses of the usage-based method in the previous section and proposed the hybrid approach as a solution to overcome these shortcomings. In order to assess the success of the proposed method in this regards, we need metrics that directly address these characteristics of the system. Thus, metrics beyond the ones used in evaluation of the usage-based method in the previous section should be used. We used the following metrics for this purpose, many of which were used by Bose *et al.* (2007). We also used some modifications of these metrics as needed. The metrics used are:

- **Recommendation Accuracy** *(RA)*: Percentage of correct recommendations between all the recommendations made by the system. A correct recommendation is, as before, a specific recommended web page that the user chooses to visit. These recommendations are generated in the hybrid approach by applying one of the page selection methods.
- **Predictive Ability** *(PA)*: Percentage of pages recommended at least once. Bose *et al.* (2007) mention this metric as one that measures how useful the recommendation algorithm is.
- **Prediction Strength** *(PS)*: Measures the average number of recommendation the system makes in each state (for each sequence of page visits). This metric aims at evaluating the ability of the recommender in generating recommendations for various scenarios of user behavior. It can specially reflect the performance of the system in the presence of the "new state" problem.

- **Shortcut Gain***(SG)*: average percentage of pages skipped because of recommendations. This is the same metric we used to evaluate the usage-based approach.
- **Recommendation Quality***(RQ):* average rank of a correct recommendation in the recommendation lists. This metric emphasizes the importance of ranking pages for recommendations (somehow similar to the manner in which ranking is valued in the results returned by a search engine).

Sensitivity to Visited Sequence Window Size

The first experiments were performed to evaluate system sensitivity to the size of visited concept sequence V in our states. To evaluate the choice of different window sizes, regardless of other parameters e.g. the page selection method, we used a new metric called *Concept recommendation Accuracy (CRA)* and *Concept Predictive Ability (CPA)* which are based on recommendation and visit of concepts instead of pages. For example, a recommendation of concept c_1 is considered successful if the user later visits any page p belonging to c_1, i.e. $C(p)=c_1$. Our evaluations indicate the best performances are achieved when using window sizes of 3 and 4 (Table 3). This is due to the fact that smaller values of w keep insufficient information about navigation history and larger values of w result in states that are numerous and less frequently visited, as the average session length in our data is 8.6. We choose w=3 in the rest of the experiments as it results in smaller number of states with a negligible decrease in accuracy.

Table 3. Comparison of different window sizes in the hybrid approach

Window Size	Metric		
	CRA	CPA	RQ
1	42	76	1.88
2	63	81	3.21
3	79.50	96	2.80
4	81.30	98	2.11
5	66.66	95	3.78

Comparison with Other Methods

We compared the proposed method with the previous usage-based approach *(UB-RL)* and a content-based approach that uses the info scent model to recommend pages from the whole website *(CIS)*. The latter method was used because of the promising results achieved in the system while using the page selection method based on information scent. Note that *UB-RL* has shown superior results than common usage-based methods, and is considered as the baseline usage-based method we aim to improve. We used three different methods for page selection in our hybrid approach: based on the distance from cluster mean *(HCM)*, using the frequency of occurrence in user sessions *(HFreq)* and the one based on Information Scent *(HIS)*. We also compared our method to a state of the art recommendation method proposed by Bose *et al.* (2007). This method makes use of concept hierarchies and sequence alignment methods in order to cluster user sessions and making recommendations based on the resulted clusters. It is abbreviated by *HSA* in the results. The results presented here are based different experiments of having 3, 5 and 10 as the maximum number of recommendations in each stage (length of the recommendation list).

An issue worth considering is that based on the experiments performed in the previous section (sensitivity to the *V* sequence), we have an upper bound estimation of the performance of our hybrid recommendation methods. For example, the *CRA* achieved by the system is the maximum *RA* the hybrid methods can achieve. Since now the methods have to select a specific page from a concept and we know the ability of the system in predicting the correct concept is limited by *CRA*. In fact, these results can be used to compare the performance of various page selection methods in the hybrid approaches.

As our evaluation shows (Table 4), *HIS* out performs the rest of the methods except with respect to *RA*, compared to *UB*-RL. Note that the *UB-RL* method shows a much lower *PA*, as it's a purely usage-based approach. An initial glance on the results can show the success of our hybrid methods in overcoming the shortcomings of the usage-based approach, especially in the sense of *PA* and *PS* metrics (both significant at $p<0.001$ on the *t*-test). Our hybrid approaches, especially *HIS* and *HFreq*, can also outperform the state of the art *HSA* recommendation method in almost every situation, although the better performance is marginal and less significant in *PS* measure, it is more significant on *PA* ($p<0.01$) and more emphasized and also statistically significant on RA, SG and RQ (all with $p<0.001$ on the *t*-test). The results achieved when using different lengths for recommendation lists almost show the same relative performance from different recommendation methods, while some features of the methods are more emphasized in higher or lower number of recommendations which we'll point out in the rest of this section. One important issue in analyzing the evaluation results is considering the logical dependencies that exist between various evaluation metrics, e.g. between *PS* and *RQ*. Considering dependencies, naturally there's not a single recommendation method that outperforms the rest with respect to *all* evaluation metrics. What should be noted is the importance of evaluating recommendation methods based their overall performance in all the evaluation metrics and also considering their relative performance in dependent evaluation metrics. As we will investigate further in the following subsections, we conclude from these results that our two hybrid approaches *HIS* and *HFreq* show an overall superior performance compared to the other methods and could be considered our suggestions for further development and implementation in real world applications, especially the *HIS* method which is the superior method in the majority of the metrics and the usually the second best in the rest. We will discuss the performance of various recommendation methods with respect to each metric in the following sub sections.

Predictive Ability

It can also be seen that all the hybrid approaches can achieve better predictive ability than the content based recommendation method *CIS* (significant at $p<0.001$ on the *t*-test). This issue is more emphasized when using shorter recommendation lists. This shows that semantic grouping of the web pages and then recommending a page from the *correct* can actually increase the chance of each page to be recommended appropriately. While, the *CIS* method which considers the whole set of pages as the search space is less successful in covering the web site.

Predictive Strength

Regarding the prediction strength metric, the *UB-RL* method is the weakest recommendation method, as expected. Various reasons for this phenomena such as the "new state" problem were mentioned in the previous section. On the other hand, the purely content-based *CIS* approach can achieve the perfect *PS* performance as there have always been some pages with some minimum similarity with the resulted content model. This can be an intrinsic characteristic of each content-based method, when not considering a lower bound on similarity. It should be noted that beside the number of recommendations shown by the *PS* value, the quality of the recommendation list is also of uttermost importance. In this regard, our hybrid approaches are able to achieve better results in almost every evaluation metric, while also achieving a *PS* very close to the optimal *CIS* approach. For example the *HIS* method achieves a 36% increase in compared to the baseline *UB-RL* method which is also statistically significant ($p<<0.001$). These results illustrate the strength

Table 4. Comparison of different recommendation methods

Method	Metric				
	RA	PA	PS	SG	RQ
Max. Number of Recommendation in Each Step=3					
UB-RL	**53.76**	51.06	2.73	10.26	**1.96**
CIS	35.09	67.12	2.99	7.01	2.54
HSA	45.11	93.60	2.97	21.07	2.26
HCM	38.09	91.01	**2.97**	11.33	2.39
HFreq	46.34	93.40	**2.97**	**24.11**	2.19
HIS	**51.66**	**94.10**	**2.97**	**22.31**	**2.15**
Max. Number of Recommendation in Each Step=5					
UB-RL	**49.81**	55.06	3.64	13.17	**2.21**
CIS	32.11	69.29	4.98	7.21	3.90
HSA	40.01	96.91	4.95	24.21	3.58
HCM	33.09	91.67	**4.96**	12.56	3.76
HFreq	42.12	95.91	**4.96**	**26.80**	3.11
HIS	**46.28**	**97.20**	**4.96**	**25.76**	**2.89**
Max. Number of Recommendation in Each Step=10					
UB-RL	**44.91**	58.15	5.69	14.17	**2.79**
CIS	29.82	73.12	9.96	8.14	8.11
HSA	34.31	96.91	9.79	25.18	6.27
HCM	30.09	92.23	9.82	14.62	6.97
HFreq	39.36	96.31	9.82	27.77	5.94
HIS	**42.17**	**97.20**	**9.84**	**27.95**	**5.33**

of the generalized models of user behavior, employed in the hybrid approaches, in capturing user behavior patterns and avoiding unseen navigation scenarios at a higher level of abstraction resulted from the generalized state and action model.

Recommendation Accuracy

While the *UB-RL* method receives the highest accuracy as expected, our proposed hybrid approaches *HIS* and *HFreq* are the second bests in almost every case with a rather small difference. This performance is especially important due to the fact that the hybrid approaches have lost the information at the detail level of page visits because of their generalized view of user behavior. Like any generalization this information loss is supposed to come inevitably with some loss in model accuracy. These results show the success of the page selection methods employed in *HFreq* and *HIS* and the importance of this selection. The rather low *RA* value achieved by *HCM* indicates the importance of page selection method in the process. It is also an indicator of the existing trade-off between generalized and detailed knowledge. As we can see this approach has a high *CRA* value (Table 3), but because of the information loss occurred at a higher level of abstraction and lack of an appropriate page selection method (at lower level of abstraction), it performs even worse than *CFreq* which is based on a rather simple metric, i.e. popularity of a page. The weaker performance of *CIS* (statistically significant at $p<0.001$) might be considered as further evidence in support of the importance of usage patterns in accurate inference of user information needs.

Shortcut Gain

Regarding the shortcut gain metric, the content-based *CIS* approach which makes no use of usage information receives the weakest results. The usage-based UB-RL method is able to achieve better shortcut gain in recommendations and *HIS* and *HFreq* hybrid recommendation methods achieve the best results in this regard (significant at $p<0.001$). The weaker performance of *HCM* in comparison to *UB-RL* is again due to the inappropriate page selection method in *HCM*, although it still manages to beat *CIS*, because of having a usage-based component. An interesting point is the ability of HIS and HFreq to achieve an increase of almost 100% in comparison to the usage-based approach. Of course, it should be mentioned that beside the higher accuracy and diversity of recommendations generated by these methods, the greater number of recommendation (*PS*) is also an effective factor in this regard.

Recommendation Quality

This metric shows the rank of correct recommendations in the recommendation lists. It can be seen that the *UB-RL* receives the best results in this regard, while our hybrid approaches are second bests and the content based approach is the weakest. The difference between the usage-based and the hybrid approaches is marginal in almost every case. One important issue is the logical dependency between the *RQ* and the *PS* metrics. Naturally, a recommender that makes fewer recommendations is more likely to achieve lower *RQ* values, e.g. a recommender that does not make more than 2 recommendations will definitely have $RQ \leq 2$. In fact, it is more appropriate to consider *RQ* in respect to the *PS* metric, e.g. the ratio *RQ/PS*. Considering this, we can see that the *HIS* method has better performance between all recommendation methods used in the experiments (significant at $p<0.001$ compared to all the baseline methods).

CONCLUSION AND FUTURE WORKS

In this chapter we presented novel web page recommendation methods based on reinforcement learning. First a usage-based method for web recommendation was proposed, which was based the reinforcement learning paradigm. This system learns to make recommendations from web usage data as the actions it performs in each situation rather than discovering explicit patterns from the data. We modeled web page recommendation as a Q-Learning problem and trained the system with common web usage logs. System performance was evaluated under different settings and in comparison with other methods. Our experiments showed promising results achieved by exploiting reinforcement learning in web recommendation based on web usage logs.

Afterwards we described a method to enhance our solution based on reinforcement learning, devised for web recommendations from web usage data. We showed the restrictions that a usage-based system inherently suffers from (e.g. low coverage on items, inability to generalize, etc.) and demonstrated how combining conceptual information regarding the web pages can improve the system. Our evaluation results show the flexibility of the proposed RL paradigm to incorporate different sources of information and to improve overall the quality of recommendations.

There are other alternatives that can potentially improve the system and constitute our future work. In the case of the reward function used, various implicit feedbacks from the user rather than just the fact that the user had visited the page can be used, such as those proposed in (Zhang & Seo, 2001). Another option is using a more complicated reward function rather than the linear combination of factors; a learning structure such as neural networks is an alternative. The hybrid method can also be extended in various ways. One is to find more sophisticated methods for organizing a website into a concept hierarchy. More accurate methods of assessing implicit feed-back can also be used to derive a more precise reward function. Integration of other sources of domain knowledge e.g. website topology or a domain-ontology into the model can also be another future work for this research. Finally, devising a model to infer higher level goals of user browsing, similar to the work done in categorizing search activities can be another future direction.

Chapter 8.6
On the Use of Soft Computing Techniques for Web Personalization

ABSTRACT

Due to the growing variety and quantity of information available on the Web, there is urgent need for developing Web-based applications capable of adapting their services to the needs of the users. This is the main rationale behind the flourishing area of Web personalization that finds in soft computing (SC) techniques a valid tool to handle uncertainty in Web usage data and develop Web-based applications tailored to user preferences. The main reason for this success seems to be the synergy resulting from SC paradigms, such as fuzzy logic, neural networks, and genetic algorithms. Each of these computing paradigms provides complementary reasoning and searching methods that allow the use of domain knowledge and empirical data to solve complex problems. In this chapter, we emphasize the suitability of hybrid schemes combining different SC techniques for the development of effective Web personalization systems. In particular, we present a neuro-fuzzy approach for Web personalization that combines techniques from the fuzzy and the neural paradigms to derive knowledge from Web usage data and represent the knowledge in the comprehensible form of fuzzy rules. The derived knowledge is ultimately used to dynamically suggest interesting links to the user of a Web site.

DOI: 10.4018/978-1-60566-024-0.ch018

INTRODUCTION

The growing explosion in the amount of information and applications available on the World Wide Web has made more severe the need for effective methods of personalization for the Web information space. The abundance of information combined with the heterogeneous nature of the Web makes Web site exploration difficult for ordinary users, who often obtain erroneous or ambiguous replies to their requests. This has led to a considerable interest in Web personalization which has become an essential tool for most Web-based applications. Broadly speaking, Web personalization is defined as any action that adapts the information or services provided by a Web site to the needs of a particular user or a set of users, taking advantage of the knowledge gained from the users' navigational behavior and individual interests, in combination with the content and the structure of the Web site. In other words, the aim of a Web personalization system is to provide users with the information they want or need, without expecting them to ask for it explicitly (Nasraoui, 2005; Mulvenna, Anand, & Buchner, 2000).

The personalization process covers a fundamental role in an increasing number of application domains such as e-commerce, e-business, adaptive Web systems, information retrieval, and so forth. Depending on the application context, the nature of personalization may change. In e-commerce applications, for example, personalization is realized through recommendation systems which suggest products to clients or provide useful information in order to decide which products to purchase (Adomavicius & Thuzilin, 2005; Baraglia & Silvestri, 2004; Cho & Kim, 2004; Mobasher, 2007b; Schafer, Konstan, & Riedl, 2001). In e-business, Web personalization additionally provides mechanisms to learn more about customer needs, identify future trends, and eventually increase customer loyalty to the provided service (Abraham, 2003). In adaptive Web sites, personalization is intended to improve the organization and presentation of the Web site by tailoring information and services so as to match the unique and specific needs of users (Callan, Smeaton, Beaulieu, Borlund, Brusilovsky, Chalmers et al., 2001; Frias-Martinez, Magoulas, Chen, & Macredie, 2005). In practice, adaptive sites can make popular pages more accessible, highlight interesting links, connect related pages, and cluster similar documents together (Perkowitz & Etzioni, 1997). Finally, in information retrieval, personalization is regarded as a way to reflect the user preferences in the search process so that users can find out more appropriate results to their queries (Kim & Lee, 2001; Enembreck, Barthès, & Ávila, 2004).

The development of Web personalization systems gives rise to two main challenging problems: how to discover useful knowledge about the user's preferences from the uncertain Web data and how to make intelligent recommendations to Web users. A natural candidate to cope with such problems is **soft computing** (SC), a consortium of computing paradigms that work synergistically to exploit the tolerance for imprecision, uncertainty, approximate reasoning, and partial truth in order to provide flexible information processing capabilities and obtain low-cost solutions and close resemblance to human-like decision making. Recently, the potentiality of SC techniques (i.e., neural networks, fuzzy systems, genetic algorithms, and combinations of these) in the realm of Web personalization has been explored by researchers (e.g., Jespersen, Thorhauge, & Pedersen, 2002; Pal, Talwar, & Mitra, 2002; Sankar, Varun, & Pabitra, 2002; Yao, 2005).

This chapter is intended to provide a brief survey of the stat-of-art SC approaches in the wide domain of Web personalization, with special focus on the use of hybrid techniques. As an example, we present a neuro-fuzzy Web personalization framework. In such a framework, a hybrid approach based on the combination of techniques taken from the fuzzy and the neural paradigms is employed in order to identify **user profiles** from Web usage data and to provide dynamical predictions about Web pages to be suggested to the current user, according to the user profiles previously identified.

The content of chapter is organized as follows. In Section 2 we deal in depth with the topic of Web personalization, focusing on the use of Web usage mining techniques for the development of Web applications endowed with personalization functions. Section 3 motivates the use of soft computing techniques for the development of Web personalization systems and overviews existing systems for Web personalization based on SC methods. In Section 4 we describe a neuro-fuzzy Web personalization framework and show its application to a Web site taken as case study. Section 5 closes the chapter by drawing conclusive remarks.

WEB PERSONALIZATION

Web personalization is intended as the process of adapting the content and/or the structure of a Web site in order to provide users with the information they are interested in (Eirinaki & Vazirgiannis 2003; Mulvenna et al., 2000; Nasraoui 2005). The personalization of services that a Web site may offer is an important step towards the solution of some problems inherent in Web information space, such as alleviating information overload and making the Web a friendlier environment for its individual user, and, hence, creating trustworthy relationships between the Web site and the visitor-customer. Mobasher, Cooley, and Srivastava (1999) simply define Web personalization as the task of making Web-based information systems adaptive to the needs and interests of individual users. Typically, a personalized Web site recognizes its users, collects information about their preferences, and adapts its services in order to match the users' needs. Web personalization improves the Web experience of a visitor by presenting the information that the visitor wants to see in the appropriate manner and at the appropriate time.

In literature, many different approaches have been proposed for the design and the development of systems endowed with personalization functionality (Kraft, Chen, Martin-Bautista, & Vila, 2002; Linden, Smith, & York, 2003; Mobasher, Dai, Luo, & Nakagawa, 2001;). In the majority of the existing commercial personalization systems, the personalization process involves substantial manual work and, most of the time, significant effort for the user. A better way to expand the personalization of the Web is to automate the adaptation of Web-based services to their users. Machine learning methods have a successful record of applications to similar tasks, that is, automating the construction and adaptation of information systems (Langley, 1999; Pohl, 1996; Webb, Pazzani, & Billsus, 2001). Furthermore, the integration of machine learning techniques in larger process models, such as that of **knowledge discovery** in data (KDD or data mining), can provide a complete solution to the adaptation task. Data mining has been used to analyze data collected on the Web and extract useful knowledge leading to the so-called Web mining (Eirinaki & Vazirgiannis, 2003; Etzioni, 1996; Kosala & Blockeel, 2000; Mobasher, 2007a; Pal et al., 2002). Web mining refers to a special case of data mining which deals with the extraction of interesting and useful knowledge from Web data. Three important subareas can be distinguished in Web mining:

- *Web content mining*: Extraction of knowledge from the content of Web pages (e.g., textual data included in a Web page such as words or also tags, pictures, downloadable files, etc.).
- *Web structure mining*: Extraction of knowledge from the structural information present into Web pages (e.g., links to other pages).
- *Web usage mining*: Extraction of knowledge from usage data generated by the visits of the users to a Web site. Generally,

usage data are collected into Web **log files** stored by the server whenever a user visits a Web site.

In this chapter, we focus mainly on the field of Web usage mining (WUM) that represents today a valuable source of ideas and solutions for the development of Web personalization systems. Overviews about the advances of research in this field are provided by several other authors (e.g., Abraham, 2003; Araya et al., 2004; Cho & Kim, 2004; Cooley, 2000; Facca and Lanzi, 2005; Mobasher, 2006, 2005; Mobasher, Nasraoui, Liu, & Masand, 2006; Pierrakos, Paliouras, Papatheodorou, & Spyropoulos, 2003). In general, regardless the application context, three main steps are performed during a WUM personalization process (Mobasher, Cooley, & Srivastava, 2000):

- **Preprocessing:** Web usage data are collected and preprocessed in order to identify **user sessions** representing the navigational activities of each user visiting a Web site.
- **Knowledge discovery**: The session data representing the users' navigational behaviour are analysed in order to discover useful knowledge about user preferences in the form of user categories of user profiles.
- **Recommendation**: The extracted knowledge is employed to customize the Web information space to the necessities of users, that is, to provide tailored recommendations to the users depending on their preferences.

While preprocessing and knowledge discovery are performed in an off-line mode, the employment of knowledge for recommendation is carried out in real time to mediate between the user and the Web site the user is visiting. In the following subsections, each step of the personalization process is more deeply examined.

Preprocessing

Access log files represent the most common source of Web usage data. All the information concerning the accesses made by the users to a Web site are stored in log files in chronological order. According to the common log format (www.w3.org/Daemon/User/Config/Loggin.htm#common-logfile-format) each log entry refers to a page request and includes information such as the user's IP address, the request's date and time, the request method, the URL of the accessed page, the data transmission protocol, the return code indicating the status of the request, and the size of the visited page in terms of number of bytes transmitted. By exploiting such information, models of typical user navigational behavior can be derived and used as input to the next step of knowledge discovery. The derivation of navigational patterns from log data is achieved through a preprocessing activity that filters out redundant and irrelevant data, and selects only log entries related to explicit requests made by users. Cooley (2000) extensively discusses the methods adopted to execute data preparation and preprocessing activity. Typically Web data preprocessing includes two main tasks, namely, data cleaning and user session identification.

The aim of data cleaning is to remove from log files all records that do not represent the effective browser activity of the connected user, such as those corresponding to requests for multimedia objects embedded in the Web page accessed by the user. Elimination of these items can be reasonably accomplished by checking the suffix of the URL name (all log entries with filename suffixes such as gif, jpeg, GIF, JPEG, jpg, JPG and map are removed). Also, records corresponding to failed user requests and accesses generated by Web robots are identified and eliminated from log data. Web robots (also known as Web crawlers or Web spiders) are programs which traverse the Web in a methodical and automated manner, downloading complete Web sites in order to update the index of a search engine. This task is performed by maintaining a list of known spiders and through heuristic identification of Web robots. Tan and Kumar (2002) propose a robust technique which is able to detect, with a high accuracy, Web robots by using a set of relevant features extracted from access logs (e.g., percentage of media files requested, percentage of requests made by HTTP methods, average time between requests, etc.).

The next task of Web log preprocessing is the identification of user sessions. Based on the definitions found in different works of scientific literature, a user session can be defined as a finite set of URLs corresponding to the pages visited by a user from the moment the user enters a Web site to the moment the same user leaves it (Suryavanshi, Shiri, & Mudur, 2005). The process of segmenting the activity of each user into sessions, called sessionization, relies on heuristic methods. Spiliopoulou (1999) divides the sessionization heuristics into two basic categories: time-oriented and structure-oriented. Time-oriented heuristics establish a timeout to distinguish between consecutive sessions. The usual solution is to set a minimum timeout and assume that consecutive accesses within it belong to the same session, or set a maximum timeout, where two consecutive accesses that exceed it belong to different sessions. On the other hand, structure-oriented heuristics consider the static site structure or they refer to the definition of conceptual units of work to identify the different user sessions. More recently, Spiliopoulou, Mobasher, Berendt, and Nakagawa (2003) have proposed a framework to measure the effectiveness of such heuristics and the impact of different heuristics on various Web usage mining tasks.

Knowledge Discovery

After preprocessing, the next step of a Web personalization process consists in discovering knowledge from data in the form of user models or profiles embedding the navigational behavior by expressing the common interests of Web visitors. Statistical and data mining techniques have been widely applied to derive models of user navigational behavior starting from Web usage data (Facca & Lanzi 2005; Mobasher, 2005; Pierrakos et al., 2003). In particular, analysis techniques of Web usage data can be grouped into three main paradigms: association rules, sequential patterns, and **clustering** (Han and Kamber (2001) detail an exhaustive review).

Association rules are used to capture relationships among Web pages which frequently appear in user sessions, without considering their access ordering. Typically, an association rule is expressed in the form:“A.html, B.html C.html”which states that if a user has visited page A.html and page B.html, it is very likely that in the same session the same user also visits page C.html. This kind of approach has been used in Joshi, Joshi, and Yesha (2003), and Nanopoulus, Katsaros, and Manolopoulos (2002), while some measures of interest to evaluate association rules mined from Web usage data have been proposed by Huang, Cercone, and An (2002a), and Huang, Ng, Ching, Ng, and Cheung (200a). Fuzzy association rules, obtained by the combination of association rules and fuzzy logic, have been extracted by Wong and Pal (2001).

Sequential patterns in Web usage data detect the set of Web pages that are frequently accessed by users in their visits, considering the order that they are visited. To extract sequential patterns, two main classes of algorithms are employed: methods based on association rule mining and methods based on the use of tree structures and Markov chains. Some well-known algorithms for mining association rules have been modified to obtain sequential patterns. For example, the Apriori algorithm has been properly extended to derive two new algorithms: the AprioriAll and GSP proposed by Huang et al. (2002a) and Mortazavi-Asl (2001). An alternative algorithm based on the use of a tree structure has been presented by Pei, Han, Mortazavi-asl, and Zhu (2000). Tree structures have been also used by Menasalvas, Millan, Pena, Hadjimichael, and Marban (2002).

Clustering is the most widely employed technique to discover knowledge in Web usage data. An exhaustive overview of Web data clustering methods is provided by Vakali, Pokorný, and Dalamagas (2004). Two forms of clustering can be performed on usage data: user-based clustering and item-based clustering.

User-based clustering groups similar users on the basis of their ratings for items (Banerjee & Ghosh, 2001; Heer & Chi, 2002; Huang et al., 2001). Each cluster center is an n-dimensional vector (being n the number of items) where the *i*-th component is the average rating expressed by users in that cluster for the *i*-th item. The recommendation engine computes the similarity of an active user session with each of the discovered user categories represented by cluster centroids to produce a set of recommended items.

Item-based clustering identifies groups of items (e.g., pages, documents, products) on the basis of similarity of ratings by all users (O'Connor & Herlocker, 1999). In this case a cluster center is represented by a m-dimensional vector (being m the number of users) where the *j*-th component is the average rating given by the *j*-th user for items within the clusters. Recommendations for users are computed by finding items that are similar to other items the user has liked.

Various clustering algorithms have been used for user- and item-based clustering, such as K-means (Ungar & Foster, 1998) and divisive hierarchical clustering (Kohrs & Merialdo, 1999). User-based and item-based clustering are typically used as alternative approaches in Web personalization. Nevertheless, they can also be integrated and used in combination, as demonstrated by Mobasher, Dai, Nakagawa, and Luo (2002).

In the context of Web personalization, an important constraint to be considered in the choice of a clustering method is the possibility to derive overlapping clusters. The same user may have different goals and interests at different times. It is inappropriate to capture such overlapping interests of the users in crisp clusters. This makes fuzzy clustering algorithms more suitable for usage mining. In fuzzy clustering, objects which are similar to each other are identified by having high memberships in the same cluster. "Hard" clustering algorithms assign each object to a single cluster that is using the two distinct membership values of 0 and 1. In Web usage profiling, this "all or none" or "black or white" membership restriction is not realistic. Very often there may not be sharp boundaries between clusters and many objects may have characteristics of different classes with varying degrees. Furthermore, a desired clustering technique should be immune to noise, which is inherently present in Web usage data. The browsing behavior of users on the Web is highly uncertain and fuzzy in nature. Each time the user accesses the site, the use may have different browsing goals. The main advantage of fuzzy clustering over hard clustering is that it can capture the inherent vagueness, imprecision, and uncertainty in Web usage data. Fuzzy clustering has been largely used in the context of user profiling for Web personalization (Joshi & Joshi, 2000; Suryavanshi et al., 2005). Castellano, Mesto, Minunno, and Torsello (2007e) prove the applicability of the well-known fuzzy C-means algorithm to extract user profiles. Nasraoui, Krishnapuram, and Joshi (1999) propose a relational fuzzy clustering algorithm named relational fuzzy clustering–maximal density estimator (RFC-MDE). Nasraoui and Frigui (2000) propose a competitive agglomeration relational data (CARD) algorithm to cluster user sessions. A hierarchical fuzzy clustering algorithm has been proposed by Dong and Zhuang (2004) to discover the user access patterns in an effective manner.

Recommendation

Once user preferences are understood by analyzing the derived user profiles, personalized services can be provided to each user, such as sending targeted advertisement to the connected users, adapting the content/structure of the Web site to the user needs, providing a guide to the user navigation, and so forth. Personalization functions can be accomplished in a manual or in an automatic and transparent manner for the user. In the first case, the discovered knowledge has to be expressed in a comprehensible manner for humans, so that knowledge can be analyzed to support human experts in making decisions. To accomplish this task, different approaches have been introduced in order to provide useful information for personalization. An effective method for presenting comprehensive information to humans is the use of visualization tools such as WebViz (Pitkow & Bharat, 1994) that represents navigational patterns as graphs. Reports are also a good method to synthesize and to visualize useful statistical information previously generated. Personalization systems as WUM (Spiliopoulou & Faulstich, 1998) and WebMiner (Cooley, Tan, & Srivastava, 1999) use SQL-like query mechanisms for the extraction of rules from navigation patterns.

Nevertheless, decisions made by the user may create delay and loss of information. A more interesting approach consists of the employment of Web usage mining for personalization. In particular, the knowledge extracted from Web data is automatically exploited to adapt the Web-based system by means of one or more of the personalization functions.

Various approaches can be used for generating a personalized experience for users. These are commonly distinguished in rule-based filtering, content-based filtering, and collaborative or social filtering (Mobasher et al., 2000). In rule-based filtering, static user models are generated through the registration procedure of the users. To generate personalized recommendations, a set of rules is specified, related to the content which is provided to the users with different models. Among the several products which adopt the rule-based filtering approach, Yahoo (Manber, Patel, & Obison, 2000) and Websphere Personalization (IBM) constitute two valid examples. Content-based filtering systems generate recommendations on the basis of the items previously rated by a user. The user profile is obtained by considering the content description of the items and it is exploited to predict a rating for previously unseen items. Examples of systems which adopt this personalization approach are represented by Personal WebWatcher (Mladenic, 1996), NewsWeeder (Lang, 1994), and Letizia (Liebermann & Letizia, 1995). Collaborative filtering systems are based on the assumption that users preferring similar items have the same interests. Personalization is obtained by searching for common features in the preferences of different users which are usually expressed explicitly in the form of item ratings or also in a dynamical manner through the navigational patterns extracted from usage data. Currently, collaborative filtering is the most employed approach of personalization. Amazon.com (Linden et al., 2003) and Recommendation Engine represent two major examples of collaborative filtering systems.

SOFT COMPUTING TECHNIQUES FOR WEB PERSONALIZATION

The term soft computing (SC) indicates a collection of methodologies that work synergistically to find approximate solutions for real-world problems which contain various kinds of inaccuracies and uncertainties. The guiding principle is to devise methods of computation that lead to an acceptable solution at low cost by seeking for an approximate solution to an imprecisely/precisely formulated problem. Computing paradigms underlying SC are:

- Neural computing that supplies the machinery for learning and modeling complex functions;
- Fuzzy logic computing that gives mechanisms for dealing with imprecision and uncertainty underlying real-life problems; and

- Evolutionary computing that provides algorithms for optimization and searching.

Systems based on such paradigms are neural networks (NN), fuzzy systems (FS), and genetic/evolutionary algorithms (GA/EA). Rather than a collection of different paradigms, SC is better regarded as a partnership in which each of the partners provides a methodology for addressing problems in a different manner. From this perspective, the key-points and the shortcomings of SC paradigms appear to be complementary rather than competitive. Therefore, it is a natural practice to build up integrated strategies combining the concepts of different SC paradigms to overcome limitations and exploit advantages of each single paradigm (Hildebrand, 2005; Tsakonas, Dounias, Vlahavas, & Spyropoulos 2002). This relationship enables the creation of hybrid computing schemes which use neural networks, fuzzy systems, and evolutionary algorithms in combination. An inspection of the multitude of hybridization strategies proposed in literature which involve NN, FS, and GA/EA would be somewhat impractical. It is however straightforward to indicate **neuro-fuzzy** (NF) **systems** as the most prominent representatives of hybridizations in terms of the number of practical implementations in several application areas (Lin & Lee, 1996; Nauck, Klawonn, & Kruse, 1997). NF systems use NN to learn and fine tune rules and/or membership functions from input-output data to be used in a FS (Mitra & Pal, 1995). With this approach, the main drawbacks of NN and FS are the black box behavior of NN and the lack of learning mechanism in FS are avoided. NF systems automate the process of transferring expert or domain knowledge into fuzzy rules, hence, they are basically FS with an automatic learning process provided by NN, or NN provided with explicit form of knowledge representation.

In the last few years, the relevance of SC methodologies to Web personalization tasks has drawn the attention of researchers, as indicated in a recent review (Frias-Martinez et al., 2005). Indeed, SC can improve the behavior of Web-based applications, as both imprecision and uncertainty are inherently present in the Web activity. Web data, being unlabeled, imprecise/incomplete, heterogeneous, and dynamic, appear to be good candidates to be mined in the SC framework. Besides, SC seems to be the most appropriate paradigm in Web usage mining where, being human interaction its key component, issues such as approximate queries, deduction, personalization, and learning have to be faced. SC methodologies, being complementary rather than competitive, can be successfully employed in combination to develop intelligent Web personalization systems. In this context, NN with self organization abilities are typically used for pattern discovery and rule generation. FS are used for handling issues related to incomplete/imprecise Web data mining, understandability of patterns, and explicit representation of Web recommendation rules. EA are mainly used for efficient search and retrieval. Finally, various examples of combination between SC techniques can be found in the literature concerning Web personalization, ranging from very simple combination schemas to more complicated ones. An example of simple combination is by Lampinen and Koivisto (2002), where user profiles are derived by a clustering process that combines a fuzzy clustering (the fuzzy C-means clustering) and a neural clustering (using a self-organising map). A Kuo and Chen (2004) discuss a more complex form of hybridization using all the three SC paradigms together, and also design a recommendation system for electronic commerce using fuzzy rules obtained by a combination of fuzzy neural networks and genetic algorithms. Here, fuzzy logic has also been used to provide a soft filtering process based on the degree of concordance between user preferences and the elements being filtered.

NF techniques are especially suited for Web personalization tasks where knowledge interpretability is desired. One of these tasks is the extraction of association rules for recommendation. Gyenesei (2000) explores how fuzzy association rules understandable to humans are learnt from a database containing both quantitative and categorical attributes by using a neuro-fuzzy approach like the one proposed by Nauck (1999). Lee (2001) uses a NF system for recommendation in an e-commerce site. Stathacopoulou, Grigoriadou, and Magoulas (2003) and Magoulas, Papanikolau, and Grigoriadou (2001) use a NF system to implement a classification/recommendation system with the purpose of adapting the contents of a Web course according to the model of the student. Recently Castellano, Fanelli, and Torsello (2007d) have proposed a Web personalization approach that uses fuzzy clustering to derive user profiles and a neural-fuzzy system to learn fuzzy rules for dynamic link recommendation. The next section is devoted to outlining the main features of our approach, in order to give an example of how different SC techniques can be used synergistically to perform Web personalization.

A NEURO-FUZZY WEB PERSONALIZATION SYSTEM

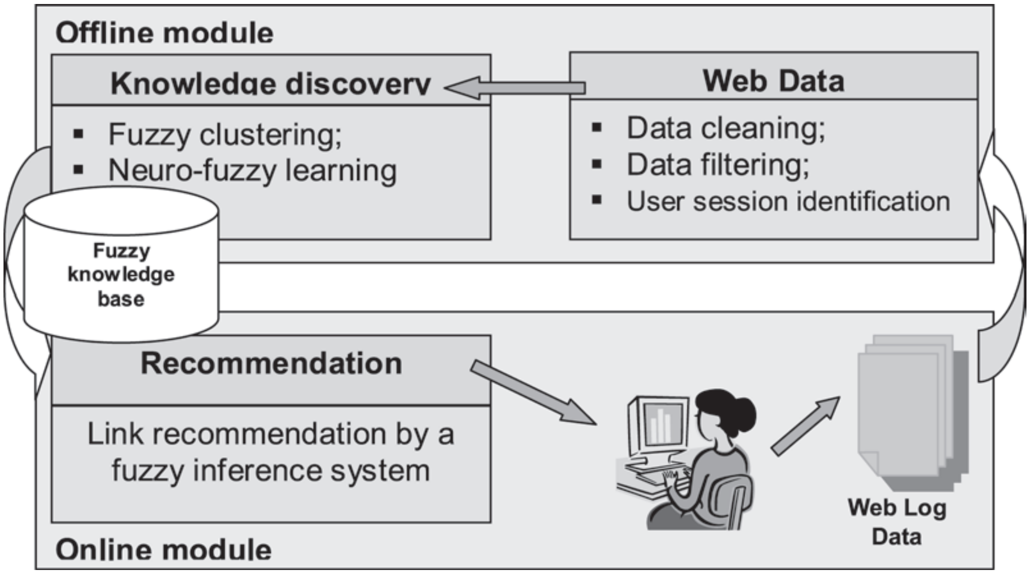
In this section, we describe a WUM personalization system for dynamic link suggestion based on a neuro-fuzzy approach. A fuzzy clustering algorithm is applied to determine user profiles by grouping preprocessed Web usage data into session categories. Then, a hybrid approach based on the combination of the fuzzy reasoning with a neural network is employed in order to derive fuzzy rules useful to provide dynamical predictions about Web pages to be suggested to the active user, according to user profiles previously identified.

According to the general scheme of a WUM personalization process described in section 3, three different phases can be distinguished in our approach:

- **Preprocessing** of Web log files in order to extract useful data about URLs visited during user sessions.
- **Knowledge discovery** in order to derive user profiles and to discover associations between user profiles and URLs to be recommended.
- **Recommendation** in order to exploit the knowledge extracted through the previous phases to dynamically recommend interesting URLs to the active user.

As illustrated in Figure 1, two major modules can be distinguished in the system: an off-line module that performs log data preprocessing and knowledge discovery, and an online module that recommends interesting Web pages to the current user on the basis of the discovered knowledge. In particular, during the preprocessing task, user sessions are extracted from the log files which are stored by the Web server. Each user session is represented by one record which registers the accesses exhibited by the user in that session. Next, a fuzzy clustering algorithm is executed on these records to group similar sessions into session categories representing user profiles. Finally, starting from the extracted user profiles and the available data about user sessions, a knowledge base expressed in the form of fuzzy rules is extracted via a neuro-fuzzy learning strategy. Such a knowledge base is exploited during the recommendation phase (performed by the online module) to dynamically suggest links to Web pages judged interesting for the current user. Specifically, when a user requests a new page, the online module matches the user's current partial session with the session categories identified by the off-line module and derives the degrees of relevance for URLs by means of a fuzzy inference process. In the following, we describe in more detail all the tasks involved in the Web personalization process.

Figure 1. The scheme of the proposed Web personalization system



Preprocessing

The aim of the preprocessing step is to identify user sessions starting from the information contained in a Web log file. Preprocessing of access log files is performed by means of log data preprocessor (LODAP) (Castellano, Fanelli, & Torsello, 2007a), a software tool that analyzes usage data stored in log files to produce statistics about the browsing behavior of the users visiting a Web site and to create user sessions by identifying the sequence of pages accessed by each visitor. LODAP preprocesses log data into three steps: data cleaning, data structuration, and data filtering. During data cleaning, Web log data are cleaned from the useless information in order to retain only records corresponding to the explicit requests of the users (i.e. requests with an access method different from "GET," failed and corrupt requests, requests for multimedia objects, and visits made by Web robots are removed). Next, significant log entries are structured into user sessions. In LODAP, a user session is defined as the finite set of URLs accessed by a user within a predefined time period (in our work, 25 minutes). Since the information about the user login is not available, user sessions are identified by grouping the requests originating from the same IP address during the established time period. The set of all users (IP) is defined by $U = \left\{u_1, u_2, \ldots, u_{n_U}\right\}$ and a user session is defined as the set of accesses originating from the same user (IP) within a predefined time period. Formally, a user session is represented as a triple $\mathbf{s}_i = \left\langle u_i, t_i, \mathbf{p}_i \right\rangle$ where $u_i \in U$ represents the user identifier, t_i is the total time access of the *i*-th session, and $\mathbf{p}_i$ is the set of all pages requested during the *i*-th session. More in detail,

$$\mathbf{p}_i = \left\langle \left(p_{i1}, t_{i1}, N_{i1}\right), \left(p_{i2}, t_{i2}, N_{i2}\right), \ldots, \left(p_{in_i}, t_{in_i}, N_{in_i}\right) \right\rangle$$

where p_{ik} is the *k*-th URL visited during the i-th session, *t*ik is the total access time to page p_{ik}, and N_{ik} represents the number of accesses to page *p*ik during the *i*-th session. Summarizing, after data structuration, a collection $S = \left\langle \mathbf{s}_1, \mathbf{s}_2, \ldots, \mathbf{s}_{n_s} \right\rangle$ of n_s sessions is identified from the log data. Finally, LODAP applies a data filtering process in order to remove requests for very low support URLs, that is, requests to pages which do not appear in a sufficient number of sessions, and requests for very high support URLs, that is, requests to pages which appear in nearly all sessions. Also, all sessions that include a very low number of visited URLs are removed. Hence, after data filtering, only m page requests (with $m \leq n_P$) and only n sessions (with $n \leq n_S$) are retained.

Once user sessions have been identified by LODAP, we create a visitor behavior model by defining a measure expressing the interest degree of the users for each visited page during a session. In our approach, we measure the interest degree for a page as the average access time on that page. Precisely, the interest degree for the *j*-th page in the *i*-th user session is defined as $ID_{ij} = t_{ij} / N_{ij}$ where t_{ij} is the overall time spent by the user on the *j*-th page and N_{ij} is the number of accesses to that page during the *i*-th session. Hence, we model the visitor behavior of each user through a pattern of interest degrees for all pages visited by that user. Since the number of pages visited by different users may vary, visitor behavior patterns may have different dimensions. To obtain a homogeneous behavior model for all users, we translate behavior patterns into vectors having the same dimension equal to the number *m* of pages retained by LODAP after page filtering. In particular, the behavior of the *i*-th user $i = 1, \ldots, n$) is modeled as a vector $\mathbf{b}_i = \left(b_{i1}, b_{i2}, \ldots, b_{im}\right)$ where

$$b_{ij} = \begin{cases} ID_{ij} & \text{if page } p_j \text{ is visited during session } \mathbf{s}_i \\ 0 & \text{otherwise} \end{cases}$$

Summarizing, we model the visitor behaviors by a $n \times m$ matrix $\mathbf{B} = \left[b_{ij}\right]$ where each entry represents the interest degree of the *i*-th user for the *j*-th page. Based on this matrix, visitors with similar preferences can be successively clustered together to create user profiles, as described in the following subsection.

Knowledge Discovery

In our approach, the knowledge discovery phase involves the creation of user profiles and the derivation of recommendation rules. This is performed by rule extraction for Web recommendation (REXWERE) (Castellano, Fanelli, & Torsello, 2007b), a software tool designed to extract knowledge from user sessions identified by LODAP. REXWERE employs a hybrid approach based on the combination of fuzzy reasoning and neural learning to extract knowledge in two successive phases: user profiling and fuzzy rule extraction. In user profiling, similar user sessions are grouped into clusters (user profiles) by means of a fuzzy clustering algorithm. Then, a neuro-fuzzy approach is applied to learn fuzzy rules which capture the association between user profiles and Web pages to be recommended. These recommendation rules are intended to be exploited by the online component of a WR system that dynamically suggests links to interesting pages for a visitor of a Web site, according to the profiles the user belongs to. A key feature of REXWERE is the wizard-based interface that guides the execution of the different steps involved in the extraction of knowledge

Figure 2. The start-up panel of REXWERE

for recommendation. Figure 2 shows the start-up panel of REXWERE.

Starting from the behavior data derived from user sessions, REXWERE extracts recommendation rules in two main phases:

1. User profiling, that is, the extraction of user profiles through clustering of behavior data.
2. Fuzzy rule extraction, that is, the derivation of a set of rules that capture the association between the extracted user profiles and Web pages to be recommended. This task is carried out through three modules:
    - The *dataset creation* module which creates the training set and the test set needed for the learning of fuzzy rules;
    - The *rule extraction* module that derives an initial fuzzy rule base by means of an unsupervised learning; and
    - The *rule refinement* module that improves the accuracy of the fuzzy rule base by means of a supervised learning.

As result, REXWERE provides in output a set of fuzzy recommendation rules to be used as knowledge base in an online activity of dynamic link suggestion.

Discovery of User Profiles

The first task of REXWERE is the extraction of user profiles that categorize user sessions on the basis of similar navigational behaviors. This is accomplished by means of the *profile extraction* module that is based on a clustering approach. Clustering algorithms are widely used in the context of user profiling since they have the capacity to examine large quantity of data in a fairly reasonable amount of time. In particular, fuzzy clustering techniques seem to be particularly suited in this context because they can partition data into overlapping clusters (user profiles). Due to this peculiar characteristic, a user may belong to more than one profile with a certain membership degree. Two fuzzy clustering algorithms are implemented in REXWERE to extract user profiles:

- The well-known fuzzy C-means (FCM) algorithm (Castellano et al., 2007d), that belongs to the category of clustering algorithms working on object data expressed in the form of feature vectors.
- The CARD+ algorithm (Castellano, Fanelli, & Torsello, 2007c), a modified version of the competitive agglomeration relational data algorithm (Nasraoui & Frigui, 2000), which works on relational data representing the pairwise similarities (dissimilarities) between objects to be clustered.

These two algorithms differ in some features. While the FCM directly works on the behavior matrix **B** containing the interest degrees of each user for each page, CARD+ works on a relation matrix containing the dissimilarity values between all pairs of behavior vectors (rows of matrix **B**). Moreover, one key feature of CARD+ is the ability to automatically determine the final number of clusters starting from an initial random number. On the contrary, the FCM requires the number of clusters to be fixed in advance. In this case, the proper number of profiles is established by calculating the Xie-Beni index (Halkidi, Batistakis, & Vazirgiannis, 2002) for different partitions corresponding to different number of clusters; the partition with the smallest value of the Xie-Beni index corresponds to the optimal number of clusters for the available input data.

Both the FCM and the CARD+ provide the following results:

- *C* cluster centers (user profiles) represented as vectors $\mathbf{v}_c = \left(v_{c1}, v_{c2}, \ldots, v_{cm}\right)$ with

$c = 1,\dots,C$

- A fuzzy partition matrix $\mathbf{U} = \left[u_{ic}\right]_{i=1,\dots,n}^{c=1,\dots,C}$ where each component u_{ic} represents the membership degree of the *i*-th user to the *c*-th profile.

These results are used in the successive knowledge discovery task performed by REXWERE.

Discovery of Recommendation Rules

Once profiles have been extracted, REXWERE enters in the second knowledge extraction phase, that is, the extraction of fuzzy rules for recommendation. Such rules represent the knowledge base to be used in the ultimate online process of link recommendation. Each recommendation rule expresses a fuzzy relation between a behavior vector $\mathbf{b} = \left(b_1, b_2, \dots, b_m\right)$ and relevance of URLs in the following form:

IF (*b*1**is***A*1k) AND … AND (*b*m is *A*mk) THEN (relevance of URL_1 is *y*1k) AND … AND (relevance of URL_m is *y*1k)

for $k = 1,..,K$ where *K* is the number of rules, *A*jk (*j*=1,…, *m*) are fuzzy sets with Gaussian membership functions defined over the input variables *b*j, and y_{jk} are fuzzy singletons expressing the relevance degree of the *j*th URL.

The main advantage of using a fuzzy knowledge base for recommendation is the readability of the extracted knowledge. Actually, fuzzy rules can be easily understood by human users since they can be expressed in a linguistic fashion by labelling fuzzy sets with linguistic terms such as LOW, MEDIUM, and HIGH. Hence, a fuzzy rule for recommendation can assume the following linguistic form:

IF (the degree of interest for URL_1 is LOW) AND … AND (the degree of interest for URL_m is HIGH) THEN (recommend URL_1 with relevance 0.3) AND … AND (recommend URL_m with relevance 0.8)

Such fuzzy rules are derived through a hybrid strategy based on the combination of fuzzy reasoning with a specific neural network that encodes in its structure the discovered knowledge in form of fuzzy rules. The network is trained on a set of input-output samples describing the association between user sessions and preferred URLs. Precisely, the training set is a collection of *n* input-output vectors: $\mathbf{T} = \left\langle\left(\mathbf{b}_i, \mathbf{r}_i\right)\right\rangle_{i=1,\dots,n}$ where the input vector **b**i represents the behavior vector of the *i*-th user and the desired output vector $\mathbf{r}_i$ expresses the relevance degrees associated to the *m* URLs for the *i*-th visitor. To compute such relevance degrees, we exploit information embedded in the profiles extracted through fuzzy clustering. Precisely, for each behavior vector **b**i we consider its membership values $\left\{u_{ic}\right\}_{c=1,\dots,C}$ in the fuzzy partition matrix **U**. Then, we identify the two top matching profiles $c_1, c_2 \in \left\{1,..,C\right\}$ as those with the highest membership values. The relevance degrees in the output vector $\mathbf{r}_i = \left(r_i^1, r_i^2, \dots, r_i^m\right)$ are hence calculated as follows: $r_i^j = u_{ic}v_{ic_1} + u_{ic}v_{ic_2}$ for $j = 1,\dots,m$ and $i = 1,\dots,n$. Once the training set has been constructed, the neural network can enter the learning phase to extract the knowledge embedded into training set and represent it as a collection of fuzzy rules. The learning is articulated in two steps. The first step is based on an unsupervised learning, based on a rival penalized mechanism, which provides a clustering of the behavior vectors and the definition of an initial fuzzy rule base. In this step, the structure and the parameters of fuzzy rules are identified. Successively, the obtained knowledge base is refined by a supervised learning process. Here, fuzzy rule parameters are tuned via supervised learning to improve the accuracy of the derived knowledge. Major details on the algorithms underlying the learning strategy can be retrieved in the work of Castellano, Castiello, Fanelli, and Mencar (2005).

Recommendation

The ultimate task of our Web personalization approach is the online recommendation of links to Web pages judged interesting for the current user of the Web site. Specifically, when a new user accesses the Web site, an online module matches the user's current partial session against the fuzzy rules currently available in the knowledge base and derives a vector of relevance degrees by means of a fuzzy inference process.

Formally, when a new user has access to the Web site, an active user's current session is created in the form of a vector $\mathbf{b}^0$. Each time the user requests a new page, the vector is updated. To maintain the active session, a sliding window is used to capture the most recent user's behavior. Thus, the partial active session of the current user is represented as a vector $\mathbf{b}^0 = \left(b_1^0, \ldots, b_m^0\right)$ where some values are equal to zero, corresponding to unexplored pages.

Based on the set of *K* rules generated through the neural learning described above, the recommendation module provides URL relevance degrees by means of the following fuzzy reasoning procedure:

(1) Calculate the matching degree of current behavior vector $\mathbf{b}^0$ to the *k*-th rule, for $k = 1,..,K$ by means of product operator:

$$\mu_k\left(\mathbf{b}^0\right) = \prod_{j=1}^{n} \mu_{jk}\left(b_j^0\right)$$

(2) Calculate the relevance degree r_j^0 for the *j*-th URL as:

$$r_j^0 = \frac{\sum_{k=1}^{K} r_{jk}\mu_k\left(\mathbf{b}^0\right)}{\sum_{k=1}^{K} \mu_k\left(\mathbf{b}^0\right)}, j = 1 \ldots m$$

This inference process provides the relevance degree for all the considered *m* pages, independently on the actual navigation of the current user. In order to perform dynamic link suggestion, the recommendation module first identifies URLs that have been not visited by the current user, that is, all pages such that $b_j^0 = 0$. Then, among unexplored pages, only those having a relevance degree r_j^0 greater than a properly defined threshold α are recommended to the user. In practice, a list of links is dynamically included in the page currently visited by the user.

A Case Study

The proposed Web personalization approach was applied on a Web site targeted to young users (average age 12 years old), that is, the Italian Web site of the Japanese movie Dragon Ball (www.dragonballgt.it). This site was chosen because of its high daily number of accesses (thousands of visits each day).

The LODAP system was used to identify user sessions from the log data collected during a period of 24 hours. After data cleaning, the number of requests was reduced from 43,250 to 37,740 that were structured into 14,788 sessions. The total number of distinct URLs accessed in these sessions was 2,268. Support-based data filtering was used to eliminate requests for URLs having a number of accesses less than 10% of the maximum number of accesses, leading to only 76 distinct URLs and 8,040 sessions. Also, URLs appearing in more than 80% of sessions (including the site entry page) were filtered out, leaving 70 final URLs and 6,600 sessions. In a further filtering step, LODAP eliminated short sessions, leaving only sessions with at least three distinct requests. We obtained a final number of 2,422 sessions. The 70 pages in the Web site were labeled with a number (see Table 1) to facilitate the analysis of results. Once user sessions were identified and visitor behavior models were derived by calculating the interest degrees of each user for each page, leading to a 2422x70 behavior matrix.

Table 1. Description of the pages in the Web site

Pages	Content
1	Home page
2	Comments by users
3,…,12	Pictures related to the movie
13,…,18	Pictures of characters
19, 26, 27	Matches
20, 21, 36, 47, 48	Services (registration, login,…)
22, 23, 25, 28, ..., 31, 50, 51	General information about the movie
32, ..., 35, 55	Entertainment (games, videos,...)
37, ..., 46, 49, 52, ..., 54, 56	Description of characters
57, ..., 70	Galleries

Next, the two fuzzy clustering algorithms implemented in REXWERE were applied to the behavior matrix in order to obtain clusters of users with similar navigational behavior. Several runs of FCM were carried out with different number of clusters (C=30, 20, 15, 10). For each trial, we analyzed the obtained cluster center vectors and we observed that many of them were identical. Hence, an actual number of three clusters were found in each run. Also, a single run of the CARD+ was carried out by setting a maximum number of clusters equal to C=15. As a result, this clustering algorithm provided three clusters, confirming the results obtained by the FCM algorithm. This demonstrated that three clusters were enough to model the behavior of all the considered users. Table 2 summarizes the three clusters obtained by CARD+ that are very similar to those obtained after different trials of FCM. For each cluster, the cardinality and the first eight (most interesting) pages are displayed. It can be noted that some pages (e.g., Pages 12, 22, and 28) appear in more than one cluster, thus showing the importance of producing overlapping clusters. In particular, Page 28 (i.e., the page that lists the episodes of the movie) appears in all the three clusters with the highest degree of interest.

An interpretation of the three clusters revealed the following profiles:

- Profile 1. Visitors in this profile are mainly interested in pictures and descriptions of characters.
- Profile 2. These visitors prefer pages that link to entertainment objects (games and video)
- Profile 3. These visitors are mostly interested in matches among characters.

A qualitative analysis of these profiles made by designer of the considered Web site confirmed that they correspond to real user categories reflecting the interests of the typical site users.

The next step was the creation of recommendation rules starting from the extracted user profiles. A neural network with 70 inputs (corresponding to the components of the behavior vector) and 70 outputs (corresponding to the relevance values of the Web pages) was considered. The network was trained on a training set of 1,400 input-output samples derived from the available 2,000 behavior patterns and from the three user profiles, as described in Section 5.2.2. The remaining 600 samples were used for testing. The training of the network was stopped when the error on the training set dropped below 0.01, corresponding to a testing error of 0.03.

The derived fuzzy rule base was integrated into the online recommendation module to infer the relevance degree of each URL for the active user. These relevance degrees were ultimately used to suggest a list of links to unexplored pages retained interesting to the current user. To perform link recommendation, the navigational behavior of the active user was observed during a temporal window of 3 minutes in order to derive the behavior pattern corresponding to the user's partial

Table 2. Clusters of visitor behaviour

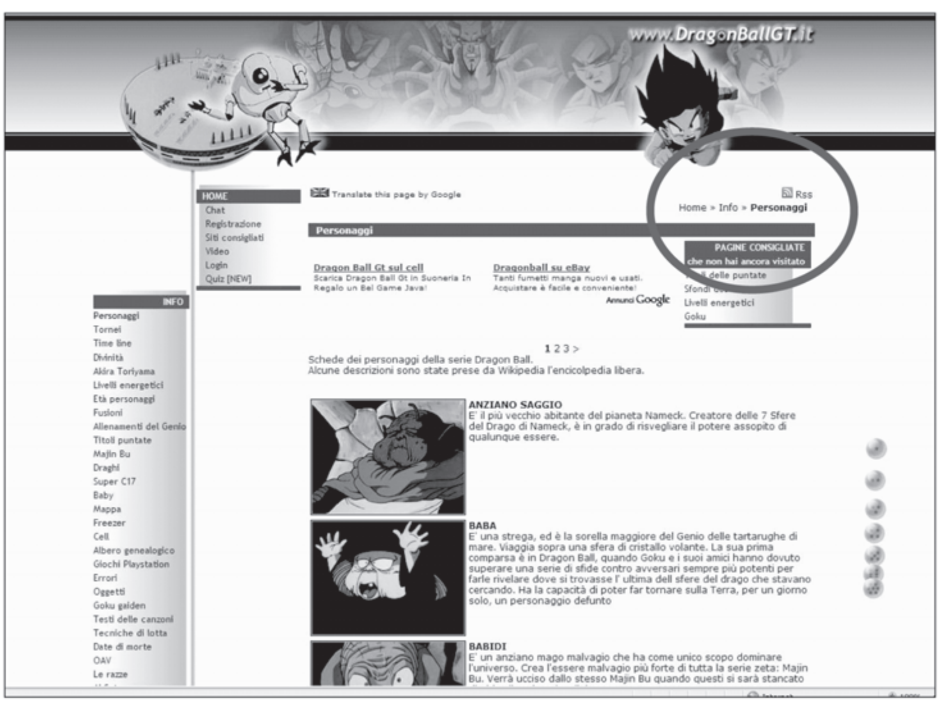
Cluster	Cardinality	Visited pages	Interest degree
1	906	(28, 12, 15, 43, 17, 22, 13, 50)	(11.1, 7.3, 6.9, 6.6, 6.59, 5.14, 4.5, 4.4)
2	599	(28, 26, 22, 55, 12, 33, 49, 32)	(80.8, 43.3, 30.1, 25.9, 24.5, 19.2, 18.1, 14.3)
3	917	(28, 12, 26, 13, 22, 9, 19, 16)	(5.3, 4.0, 3.4, 3.1, 2.6, 2.60, 2.3, 2.2)

visit. Such behavior pattern was used as input to the fuzzy rule inference process that computes the relevance degrees for all the considered 10 pages. Then, among the unexplored pages, only those having a relevance degree greater than $\alpha = 0.7$ were included in the list of links to be suggested. As an example, Figure 3 shows a page of the considered Web site after the online recommendation module has dynamically included the list of suggested links.

CONCLUSION AND FUTURE TRENDS

The rapid development of the World Wide Web as a medium for information dissemination has generated a growing interest in the domain of Web personalization that may offer a variety of functionalities in several context, such as customization, task performance support, personalized guidance, and so forth. Specifically, in personal-

Figure 3. A personalized page of the Web site. The recommended links are displayed in the up-right corner (inside the red circle)© 2008 Fabrizio Mesto. Used with permission.



ized guidance, the knowledge acquired from the analysis of users' navigational behavior (usage data) can be conveniently exploited in order to customize the Web information space to the necessities of users. As a consequence, there is growing interest in tools for automatic identification of user profiles by modeling the preferences of different user categories. Once user preferences are understood by analyzing the discovered user profiles, personalized services can be provided to each user.

In the Web personalization context, soft computing techniques emerge as valid tools to handle the ambiguity and uncertainty inherent in Web usage data. A brief survey of recent approaches to Web personalization that employ SC techniques has been presented. The survey emphasizes how most of Web personalization applications developed so far are based on combinations of SC techniques. As an example, a Web personalization system for dynamic link recommendation joining techniques from the neural and the fuzzy paradigms has been described. This neuro-fuzzy personalization system extracts knowledge from Web usage data in a twofold form: a set of fuzzy user profiles that capture preferences of similar users and a collection of fuzzy rules that describe associations between user profiles and links to be recommended.

In addition to those discussed in this chapter, there are some other aspects of Web personalization where SC is likely to play a key role. For example, user profiles generated by Web mining techniques are typically represented in a simplistic manner, by means a vector of ratings. More expressive models based on fuzzy logic could be explored in order to represent the vague and heterogeneous information characterizing user preferences. Another important facet is the ability to identify the continuous changes in interests of users and dynamically adapt user profiles according to these changes. Neural network learning algorithms based on online schemas could be investigated to cope with this issue. On the whole, hybrid approaches that synergistically combine SC methods show great potential for Web personalization, opening new research directions within the area of Web intelligence.

Chapter 8.7
Enhancing the Testability of Web Services

ABSTRACT

For the foreseeable future, testing will remain the mainstay of software quality assurance and measurement in all areas of software development, including Web services and service-oriented systems. In general, however, testing Web services is much more challenging than testing normal software applications, not because they are inherently more complex, but because of the limited control and access that users of Web services have over their development and deployment. Whereas the developers of normal applications, by definition, have full control over their application until release time, and thus, can subject them to all kinds of tests in various combinations (e.g., integration testing, system testing, regression testing, acceptance testing, etc.), users of Web services can often only test them at run-time after they have already been deployed and put into service. Moreover, users of Web services often have to share access to them with other concurrent users. In order to effectively test Web services under these conditions special measures and approaches need to be taken to enhance their testability. Right from the early phases of development, the testability of services needs to be taken into account and "designed into" services. In this chapter we consider these issues and with the aid of a case study we present a methodology that can be used to enhance the testability of Web services.

DOI: 10.4018/978-1-60566-042-4.ch010

INTRODUCTION

Service-oriented development is based on the idea of building new software applications using software "services," often built and deployed by third party organizations. It therefore assumes a fundamental separation of concerns between *service developers*, who create and offer services with no knowledge of specific applications to which they may be put, and *service users*, who assemble new applications which use the services available on the Internet or in a company's Intranet.

Since they are themselves software applications, services are typically developed and tested using the same basic practices and techniques used to develop normal software applications, and as a result, they can be expected to exhibit the same levels and variations in quality found in the general population of software applications. However, in service-oriented development, the quality of a service-based application is not just based on the inherent quality of the services it uses, it is also dependent on whether they are used or assembled in the correct way. A system assembled from perfectly correct services may still function incorrectly if it uses the services in a different way to that intended; in other words, if the system's understanding of its contract with a service is different to the service provider's.

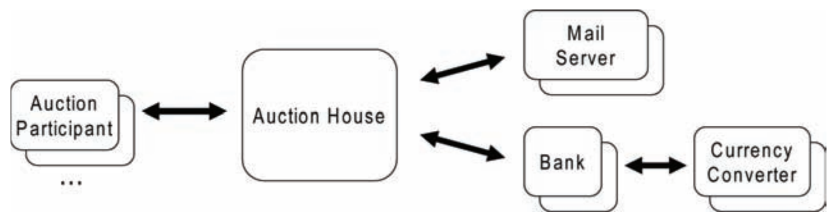
This problem exists in all component-based approaches whenever a new application is created from prefabricated parts. However, the situation is more acute in service-based development because service users have much less access to, and control over, their components than in regular component-oriented development approaches using such technologies as EJB, SPRING, or .NET. If the developers are creating all of their own components in-house, they can test larger assemblies of components while the development process is underway (integration testing). And even when some of the components are purchased from a third party, once the first version of the system has been completed they can still often test the full system under controlled conditions in the development/test environment (system testing). Finally, once a traditional component-based system has been delivered to the customer, it can be further tested in the customer's target environment to determine whether it fulfils the customer's needs (acceptance testing) before being made accessible to end users.

In general, none of these traditional testing activities can be carried out in the normal way when developing a service-oriented system, however. First, the final collection of "components" that make up an application is typically not known until deployment-time, making full integration and system testing in the traditional form impossible. Second, many of the "components" may already provide services to other users, and cannot be shut down even temporarily to participate in traditional testing activities in a controlled environment. A new application will often have to share its components with other applications and cannot assume that these will cooperate while it is in testing mode.

Although subtle, these differences have a fundamental impact on the role and goals of testing in the system development process. Because services are in effect independent, multiuser systems in their own right, new applications have to test them at run-time in a way that combines acceptance testing with integration and system testing. In other words, tests of "components" by applications can no longer be regarded as a pure verification exercise, as has traditionally been the case, but must also include an element of "validation" (Boehm, 1984). An application that is connected to a new service at run-time needs to determine whether the service does the "right thing," just as much as it needs to determine whether it does that thing "right."

Building services so that they can be tested in this way requires changes to the way they are traditionally designed and the way that tests are carried out. The purpose of this chapter is to discuss these changes and to present a methodology

Figure 1. Overview of the case study



intended to improve the testability of services. Testability characterizes how easy it is to test a system based on the information provided by it (Voas & Miller, 1995). In the next section we discuss some of the main issues involved in testing services, and describe the basic principles behind the approach. In Section 2 we explain how the basic functionality of services can be modelled in a practical way using UML, and then in Section 0 we explain how services can be extended to enhance their testability. In the following three sections we then consider how to use these enhanced services to design and apply run-time tests. Finally, in Section 0 we round up with some concluding remarks.

To present the ideas in a coherent way, we use a single case study throughout the chapter. This is a so-called "auction house" system whose job is to enable attendees of an auction to interact and participate electronically using standard mobile devices. Unlike fully electronic auction applications like E-bay, the users of this system need to be actually present at a physical auction. The system supports the auctioneer by allowing users to offer and bid for items and conduct payment transactions electronically.

In Figure 1, the auction house service is represented by the big rectangle in the middle. The figure indicates that the auction house uses two other types of services to help it deliver its functionality to auction participants' bank and mail server. The bank, in turn, uses currency converter services to deliver its functionality. It is possible that some of the internal components of the auction house might also be implemented as components, in which case the same principles can be applied to their interfaces as well. However, here we are not concerned with the internal implementation of the auction house service.

SERVICE TESTING

In the following we discuss two important issues in service testing: testing phases and test isolation.

Testing Phases

Web services are essentially software components "designed to support interoperable machine-to-machine interaction over a network" (Austin, Babir, Ferris, & Garg, 2004) (unless explicitly stated otherwise we regard the terms "service" and "Web service" as being synonymous for the purposes of this chapter). As such, they can be developed and tested according to the principle of *contract-driven design* (Meyer, 1992), which holds that the interface between a service and its users should be documented in terms of the rights and obligations of each party. Like parties in a legal contract, the idea is that each party involved in an interaction should know what it may expect and what it must provide in order for an interaction to be completed successfully. The contract therefore defines the criteria by which an interaction can be judged as having succeeded or failed.

With traditional development approaches, two basic forms of testing are used to check that a systems assembled from separate modules does what it is supposed to: "integration testing" and "acceptance testing." Integration testing is a verification technique that focuses on the testing of successively larger groupings of modules, leading up to the system as a whole (for the purpose of this discussion we regard "system testing" as a special case of integration testing). It is performed in the context of the development environment and involves the actual components that will be delivered in the final product, rather than "stubs" or "mocks" for them. According to the terminology of Boehm (1984), integration testing aims to verify that "we are building the system right" according to some well defined description of what the system should do. Acceptance testing, in contrast, is a validation technique which revolves around the testing of a deployed instance of the system in the target execution environment before it is put into service. In Boehm's terminology acceptance testing aims to validate that "we are building the right system" based on the expectations of the customer or users.

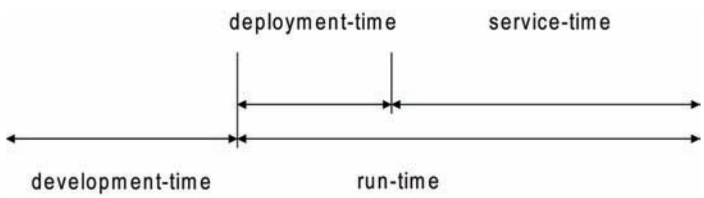
In service-oriented development, when systems are assembled from third party services, many of the assumptions which underpin these traditional testing approaches are no longer valid. Integration testing is no longer applicable in its traditional form because the precise composition of a system is not known at development-time when integration testing is traditionally performed. The notion of testing "the system" as an integrated whole at development-time no longer applies in the traditional sense therefore. Testing at development-time is still important, but its role is to test the implementation of a service's provided interface with representative implementations of its required interfaces. A "representative implementation" of a required service can either be a full working version of the service or a stub/mock which mimics the service for a few chosen test cases. Since these tests are performed at development-time and are exclusively focused on verification against a specification, we simply use the term *development-time testing* for this activity.

In the context of service-oriented development neither the notion of integration testing nor the notion of acceptance testing is fully appropriate in its traditional form. The former is not appropriate because integration testing can no longer be fully performed at development-time as has hitherto been the case. The latter is not appropriate because the testing that is performed at deployment-time should no longer focus just on validation as has traditionally been the case. Instead, the testing activities that are performed at deployment-time also need to include tests to verify the assembly of services against the system's specification. It therefore makes sense to combine the notions of integration and acceptance testing into a single activity known as *deployment-time testing*. Such a deployment-time, service testing activity serves the dual roles of validation and verification of the assembled system in its run-time environment.

For a system whose structure remains constant after initial deployment there is clearly no need to revalidate the system once it is up and running because any tests that have already been executed will not be able to uncover new problems. However, many service-oriented systems do not have a constant structure. On the contrary, an important benefit of service-oriented development is that it allows the structure of a system to be changed while it is running. If a change is made, then clearly tests performed at deployment-time may no longer be valid.

The notions of development-time and deployment-time testing are therefore not sufficient to cover the full spectrum of testing scenarios in dynamically reconfigurable service-based systems. We need to add the notion of *service-time testing* as well. Service-time tests are carried out once a system has entered service and is delivering value to users (i.e., is being used to fulfil its purpose). Deployment-time and service-time testing both take place at "run-time" in the sense that they are applied to a "running" system in its final execution environment.

Figure 2. Life-cycle phases of a system



The relationship and role of these different phases in the life-cycle of a service-oriented system are summarized in Figure 2. At the highest level of abstraction, two different phases exist, that is, the development phase, in which the system is developed and tested using representative servers in the development environment, and the run-time phase, in which an instance of the system is connected to actual servers and is running in its final execution environment. The run-time phase is divided into two subphases: the *deployment phase* and the *service phase*. In the deployment phase, the system is set up in its initial configuration and starts to run in its execution environment, but it is not yet delivering service to users. This is important because it allows testing activities to be performed under controlled conditions with known assumptions. In the service phase the system has been put into service and is delivering value to users. During service-time the assumptions that held during deployment-time may no longer be valid.

Test Isolation

As with other development abstractions, an important distinction in service-oriented development is the distinction between types and instances. Service types are classifiers in the UML sense. In other words, service types are templates that can be instantiated to create service instances with specified properties. WSDL files actually contain a mix of both concepts. The first part defines the abstract type exposed by the Web services, while the second part specifies the location and identity of an individual instance.

A common misconception about Web services is that they are stateless because they are often used as facades or wrappers to databases or legacy content providers and are not responsible for maintaining state themselves. However, Web services can actually be stateful objects whose behaviour is dependent on the history of interactions. In fact, from a programming point of view (e.g., assuming Java), Web services are like classes which expose a set of methods (operations) and can have their own internal attributes. A single Java class can even be deployed as a Web services.

From the perspective of testing, these properties of Web services create two significant complications:

1. The effects of an operation may not be the same each time it is executed (with the same arguments) due to the state of the service, and
2. The operations exposed by the service may be used by other users while a single user is trying to test it. Thus, the state of the service may not always be known before a service is invoked.

The basic problem is how run-time tests can be performed without having unintended side effects on data or state. In other words, how can the execution of tests and the execution of regular business logic for real users be separated? The testing of a service by one user should not have any effect on the delivery of services to other simultaneous users. To do this it is necessary to intercept each invocation of a service operation and check whether the invocation is part of a test or a regular service request. If the operation is executed from a test, then the test should be *isolated* from the service's response to regular requests.

Web services live in a run-time environment which frees the developer from the burden of developing the functionality which is necessary to interact with the outside world over a network. The Web service is deployed and the functionality offered by the run-time environment is immediately available. This must also include run-time testing functionality built into the run-time environment to support test execution and test isolation. An example for such an environment which the authors have developed is presented by Suliman, Paech, Borner, Atkinson, Brenner, Merdes, et al. (2006).

Several different so-called "test isolation" mechanisms can be identified. One strategy is to prioritize the execution of business logic over the execution of a test. The execution with the lower priority then has to wait. Once the high priority request has been completed, the test is then executed. This strategy can be made more rigorous by ensuring that whenever a regular request is received during the execution of a test, the execution of the test is cancelled and rescheduled.

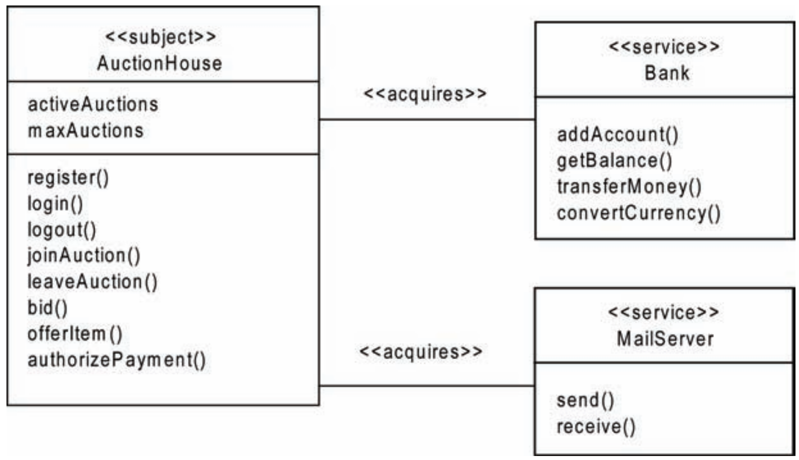
A second possible test isolation strategy is to just clone the service. A client that wishes to test a service can then work on a copy of the service rather than on the real live version that is servicing user requests. This assumes that it is possible to create a copy of the service easily (and automatically). Through a standardized interface it might even be possible to give the service developer the chance to program the cloning themselves. This would be like a service-driven cloning facility.

FUNCTIONAL INTERFACE SPECIFICATION

The first task to be performed in the development of a service is the creation of a high-level specification. The purpose of this specification is to describe the basic functionality offered by the service (the provided interface) and the basic functionality that it needs from other services (the required interface). It also describes the non-functional properties that the service offers and requires. Since a service's specification defines everything that is visible to its clients at run-time, it effectively defines the contract between instances of the service and its run-time clients and servers. In general, a service can support multiple interfaces, but for simplicity we regard these as a single composite interface. Thus, without loss of generality we regard services as having just one provided interface. The same also holds for the required interfaces. Without loss of generality we regard services as having just one required interface.

Ideally a service specification is captured in a platform independent language such as the UML, but any suitable language is acceptable. The approach described in this chapter applies the UML according to the principles of the KobrA method (Atkinson, Bayer, Bunse, Kamsties, Laitenberger, Laqua, et al., 2001), since this provides a clean separation of concerns and documents the externally visible properties of a service in a complete but easy-to-read way. A KobrA service specification involves the creation of three distinct views of a service: the structural view, which describes all structural information that a user of the service needs to be aware of, the functional view, which describes the effects of the operations exported by the service in terms of pre- and post-conditions, and the behavioural view, which describes the allowable sequences of operation invocations in terms of externally visible states and state transitions.

Figure 3. Auction house specification class diagram



Structural Specification

The structural view describes the information that potential clients of the service need to be aware of when interacting with the service. Primarily, these are the types of the parameters and return values of the service's operations, but it can also include other information such as the service's position in one or more taxonomies, or any important associations that the service maintains.

In KobrA, the structural view of a service is represented as a class diagram. The structural class diagram for the specification of the auction house service is illustrated in Figure 3.

This diagram shows the auction house service, represented as the class with stereotype <<subject>>, together with its required interfaces, represented as the classes with stereotype <<service>>. The AuctionHouse class lists the operations provided by the auction house service.

Functional Specification

The functional view of the service describes the effects of its operations. In general, one operation specification is created for each operation of the service which describes its behaviour in terms of OCL pre- and post-conditions. Figure 4 shows the operation specification of the bid() operation of the AuctionHouse.

Behavioural Specification

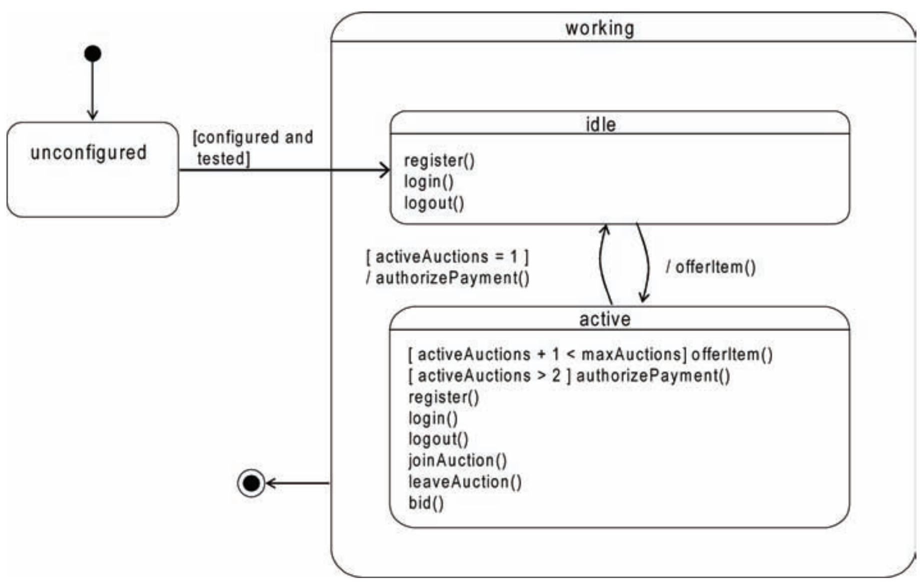
The behavioural view provides a description of any externally visible states that the service exhibits. Figure 5 shows the behavioural model for our auction house example.

The AuctionHouse has two top level states: unconfigured and working. A service enters the unconfigured state when it is first created. In this state it has not been configured and has not been connected to any of its required servers. Only when the configuration operations have been executed, the appropriate dependencies have been set, and the service has been tested the system moves into the working state. This is the state in which the system is servicing user requests. The working state has two substates, that is, idle and active. In the idle state the system is able to respond to a register(), login(), and logout() request, but since there are no active auctions it is unable to respond to requests that relate to active auctions. Only when an offerItem() operation has been invoked and an auction has been started is an AuctionHouse instance is in the active mode so that it can respond to all actions.

Figure 4. Specification of the auction house's bid() operation

Name	**bid()**
Description	
Constraints	the executing bidder is registered at the AuctionHouse
Receives	sessionId : String; bid : Money;
Returns	boolean
Sends	anActivityLogger.logBid(username, bid);
Reads	
Changes	
Rules	
Assumes	bidder is logged in; bidder is not the initiator of the current auction;
Results	if the sent bid is higher than the current highest bid, return true; otherwise return false;

Figure 5. Auction house behavioural model



Extra-Functional Requirements Definition

A service specification will usually have numerous extra-functional requirements in addition to its functional requirements. In general, these can simply be stated in the requirements document alongside the functional requirements discussed in the preceding sections. Probably one of the most important extra-functional requirements is the reliability or equivalent to the failure rate. One way to state such a requirement is to give the maximum allowed failure rate for each operation, as illustrated in Figure 6.

Alternatively, it is possible to define the probability of failure on demand (POFOD) (Sommerville, 2004). For each operation, this value gives the probability that any particular invocation

Figure 6. Reliability requirements

operation	failure rate
AuctionHouse	
register()	0.02
login()	0.03
logout()	0.10
joinAuction()	0.05
leaveAuction()	0.02
bid()	0.002
offerItem()	0.01
authorizePayment()	0.002

of the operation will fail. If the POFOD and/or the likely failure rate has been defined and the relative execution frequencies have been determined, corresponding POFOD and failure rates can be calculated and specified for the service as a whole.

TESTABLE INTERFACE DEFINITION

We refer to the properties of the service that have been defined up to this point as the *functional interface* of the service. This describes the core characteristics of the service as seen by potential users, that is, the contract that it offers. However, not all of the functionality of the service are represented in the operations of the service. Some are defined in the behavioural or structural views and, thus, are not automatically accessible to users at run-time (e.g., states). The next step in the specification process is thus to make sure that *all* behaviour and properties defined in the specification are accessible as operations, not just those operations explicitly identified and specified in the functional view. This is necessary to give users of the service a way of detecting and possibly setting the (logical) states and attributes of a service without having direct access to is its internal implementation (and thus breaking it encapsulation). Providing full access to the contract offered by a service makes it fully testable at run-time.

Information in the behavioural and structural views which is not testable via the basic *functional interface* has to be "functionalized" in the form of additional operations. This gives rise to the so-called *testable interface*. The functional interface and the testable interface together form the *extended interface*.

Interface Extension

The purpose of the testable interface is to make sure all of the semantic properties defined in the service specification are accessible as operations so that they are amenable to testing at run-time. In general this can be done with information that comes from three sources:

1. Logical attributes of the service
2. Logical states of the service
3. Extra-functional requirements

In the case of (1), operations for setting and getting the value of each logical attribute should be added. In the case of (2), operations for setting and getting (or confirming) the logical states of services should be added, and in the case of (3), operations for getting the value of each extra-functional quality-of-service (QoS) property should be added. In addition, an operation should be defined for any other semantic information of any kind in the service specification that affects the run-time behaviour of the service and is in principle measurable.

Furthermore, the testable interface could offer operations which support test isolation. These operations indicate whether the service is sensitive to testing (that means tests and business functionality cannot be performed at the same time because of the risks of destroying the service state) or whether it supports the execution of tests in parallel with the business functionality, for example, by offering a specific clone operation.

In this example it would make sense to define the following additional operations in the testable interface of the AuctionHouse:

- **Logical Attributes**
  - setActiveAuctions()
  - getActiveAuctions()
  - getMaxAuctions()
- **Logical State**
  - setIdle()
  - isIdle()
  - setActive()
  - isActive()
  - isWorking()
- **Extra-Functional Requirements**
  - getAllocatedMemory()
- **Test Isolation**
  - cloneAuctionHouse()

These operations are first class citizens of the service interface, and, thus, need to be added to the specification views developed in the previous sections. Each operation needs an operation specification, and should appear in the behavioural and structural views of the service as well. The specification of the extended interface is known as the extended specification of the service. For example, Figure 7 shows the specification of the setActive() operation.

As a result, the extended structural view is shown in Figure 8, and the extended behavioural view is shown in Figure 9.

Usage Profile Definition

Another part of the specification of a service from the perspective of testability is its so-called usage profile (Juhlin, 1992). This is composed of two parts. One part is a specification of the relative execution frequencies of the operations offered by the service. The other part is a specification of the expected distribution frequencies of the parameter values of the operations.

The simplest way to represent the usage profile is to extend the behavioural view and operation specification identified before. The behavioural view can be enhanced to show execution frequencies by showing the relative probability of each of the exit transitions from each state. The sum of the probabilities of all exit transitions from a state must equal 1. This is shown in Figure 10 below.

The assumed parameter value distribution is best described by adding additional information to the “receives” fields of the operation specifications, as illustrated in Figure 11. In this figure, the bracketed information after each parameter type defines the assumed distribution. Thus, sessionId is a String parameter with Strings values distributed uniformly and bid is parameter of type Money with values distributed according to a Poisson distribution.

RUN-TIME TESTING

Once the extended interface of the service has been fully specified it can be turned into an executable

Figure 7. Operation specification for setActive()

Name	**setActive()**
Description	sets the service to the “active” state
Results	the service is in the “active” state

Receives	sessionId : String (Uniform); bid : Money (Poisson);
…	…

system using the normal, widely available tools for implementing services. While under development it should also be tested using the typical defect testing techniques used to test software systems with a well defined interface. Any errors discovered will typically be fixed until a fully functional service is available, which is correct w.r.t. to the usual range and number of test cases. If the service is made available as a Web service, which is usually the case, the implementation process will also result in a WSDL file of the form sketched in Figure 12, which describes the extended interface to the service in a form that can be invoked via SOAP messages.

Developers of new applications can now use this service in their applications. However, in order to have confidence that the service will fulfil their needs, it is advisable for them to test the service using the features offered by the full extended interface. These tests can either be performed during the development of the application using a small, dedicated test harness, or they can be "built-in" to the client application and tested at run-time.

Figure 12. WSDL file of the auction house service

```xml

        <wsdlsoap:address location="http://localhost"/>
      </wsdl:port>
    </wsdl:service>
</wsdl:definitions>
```

In this section we discuss the various issues and strategies involved in designing such built-in, run-time tests. To put these tests into use, mechanisms must exist which define how these tests can be associated with a service, when the tests should be executed, and how a user can react to a failed test (Atkinson, Brenner, Paech, Malaka, Borner, Merdes, et al., 2006).

Analysis and Ranking

The failure of a server to fulfil a contract, as perceived by the application client, can have various consequences ranging from nothing of particular concern to the complete inability of the service to fulfil its specification. The first step in the design of the tests is therefore to analyse the likelihood and consequences of service failure to the application under development (which may be another service). The identified risks are balanced against the cost of detecting the risk and reacting to it at run-time. Based on a trade-off analysis, tests are designed for the failures with the highest risk-cost ratio. Initially, a risk and cost analysis is performed to analyze the nature of an application's dependency on a service. This is driven by the following questions:

1. What are the types of contract failures that could occur and what is the likelihood of each type occurring?
2. For each failure type, what is the consequence of that failure occurring in terms of the service's ability to provide its own

services and in terms of possible effects on the overall system in which an instance of the service might be deployed?
3. What are the estimated costs of detecting this failure in terms of the ability of the application to deliver its service?
4. What countermeasures are feasible?

For example:

A. Risk: The auction house does not meet its functional contract, for example, does not send confirmation e-mail to the right address.
   1. Low likelihood because this is standard functionality
   2. Failure can be serious for high priority e-mails
   3. Estimated cost of detection is low; could be checked when the service sends an e-mail to itself via the external e-mail service
   4. Stop using the service and choose a different service provider
B. Risk: The auction house does not meet its reliability contract.
   1. Fairly high likelihood in case of high load
   2. Failure can be serious
   3. High estimated cost as this requires quantitative testing
   4. Implement checking algorithms

The risks are ranked according to their likelihood of occurrence and their potential impact, taking into account the cost of detection and reaction. Thus, in the example the test of e-mail functionality would be ranked high since its impact is high, and the cost manageable. Also, despite the high cost, the testing of the auction house's reliability is ranked high because of the high impact.

Contract Test Case Definition

Once the goal and relative priority of each risk have been identified, the next step is to define contract test cases (CTCs) to uncover the most highly ranked contract risks. The aim of these CTCs is to uncover at run-time a failure in the service's ability to fulfil the part of the contract that leads to the risk in question.

There are two basic criteria for defining CTCs depending on whether quantitative or qualitative information is required from the execution of run-time tests. Qualitative tests return binary (pass/fail) information depending on whether or not a service fulfils a contract as understood by the client application. This form of run-time test is therefore the most basic and is the most widely applicable. Quantitative tests return a numeric measurement of the level of reliability to which a service implements the contract as understood by client application. This kind of run-time test is therefore only needed if the contract has an associated reliability requirement.

Both forms of testing rely on the ability to determine whether a particular invocation of a service's operation succeeds or fails from the perspective of the client. There are three basic ways in which such an invocation can be judged to have failed:

1. The operation completes, but returns a result that was not the expected one;
2. The operation does not complete and returns some indications to the caller that it was unable to do so (e.g., an error message); and
3. The operation does not complete within a required period of time.

In principle, all three forms can be used in both quantitative as well as qualitative testing. However, since forms (2) and (3) do not require an expected result to be determined, they are particularly suited to quantitative testing. The creation of expected results for the first form of failure has traditionally been one of the biggest stumbling blocks to quantitative testing because it is difficult if not impossible to do automatically.

Qualitative Contract Test Case Definition

The goal of qualitative CTCs is to uncover mismatches between the service provider's understanding (i.e., interpretation) of its contracts and those of the application using it. The CTCs are therefore designed to maximize the chances of uncovering contract understanding mismatches at run-time. Qualitative test cases are similar to the test cases defined in the functional and structural test case design for defect testing. However, since it is assumed that the service has already been tested at development-time to detect coding defects, the focus is on test cases which reveal problems in the service's behaviour due to dependencies on its environment or due to implicit assumptions. In general, the types of "misunderstanding" of a contract that can lead to perceived failure of a service fall into the following two categories, that is, syntactical misunderstandings and semantic misunderstandings.

Syntactical misunderstandings can arise in several parts of a provided interface. In statically typed languages such as Java, the compiler will return an error message when, for example, either a method name does not exist or parameter types of the called method do not match. It is possible to invoke an operation of a Web service without taking the nature of its interface inaccount, but in most cases, invocations are at least checked against, if not created from, the signature information in the WSDL file (such as Figure 12).

Thus, in the AuctionHouse case study, if the AuctionHouse service attempted to invoke the transferMoney() operation of the Bank service with the following type profile

transferMoney(int, int, double)

whereas the operation defined by the Bank service had the following signature

transferMoney(String, String, double).

the Java compiler will return an error. Such a misunderstanding can quite easily occur when using Web services. Since this depends on the programming language used to implement the application or using service we do not further discuss this type of misunderstanding here.

Semantic misunderstandings come from an operation's input parameters. When two or more parameters have the same type the correct order cannot be inferred unambiguously from the WDSL file. This means that the client of a service might assume a different order of input parameters than the called service, probably leading to a nunexpected result. So if, for example, the Bank has a transferMoney() operations with the following intended meaning of its parameters

transferMoney(String fromAccount, String toAccount, double amount)

while the client expects the opposite

transferMoney(String toAccount, String fromAccount, double amount)

the invocation of the operation fails. Even though this kind of semantic misunderstanding can only happen with parameters of the same type, it happens quite often. This is something that can easily be checked via a run-time test. Test cases should be defined for all operations where such parameter swapping is likely. All possible permutations of the parameters need to be checked.

When a third party service is used, it often happens that the client does not know what the valid input values are, and, thus, invokes the operation with *invalid input parameter values*. It is also unknown to the client how the used service will react to the invalid values. Services differ in the way they handle such cases. Some services use default values, others return an error message. This leads to a *different understandings of exception handling*. Therefore, the client should create tests that invoke operations with invalid (boundary) values and check the service's reaction.

If no error occurs during the execution of an operation, the called service will return an output value. The returned output and expected result can differ in various ways. An important distinction in this regard is between functional and extra-functional differences. A functional difference is, for example, the *accuracy of the output*. This kind of difference can occur when the bank uses an additional (third-party) service for converting a certain amount of money between two currencies. The output might be perfectly correct, but whereas the client expected a precision of three decimal places the bank returned a precision of only two. In contrast, extra-functional differences relate to *quality properties* such as response time. When the response time of the AuctionHouse for the bidding operation is too long, it becomes unusable. However, the quality is dependent on the whole system (environment) so that no general conclusions can be drawn from one single test case. Therefore, multiple test cases need to be run, the quality property measured (here the response time), and the average value determined. If this average value lies within a certain range, it will be classified as acceptable.

It can also happen that the service called by the client functions correctly, but still delivers a wrong output. This is the case when the called service depends on other servers in order to fulfil its provided functionality. Unfortunately, such a server usually cannot be detected directly. When the AuctionHouse uses a Bank service to access certain functionality and the bank itself uses a CurrencyConverter service then an error in the interaction between the Bank and the CurrencyConverter cannot be detected by the AuctionHouse. Constructing test cases that invoke a chain of operations is a possibility. The problem is that there might not be enough information available to construct such dependence chains.

Quantitative Contract Test Case Definition

Quantitative contract test cases are used to determine, to a given level of confidence, whether a service delivers its functionality with a level of reliability. A prerequisite for quantitative tests of a service is an extended specification which includes usage profile information of the kind outlined in Section 0. We therefore assume that all provided services have been specified according to the approach.

To attain a reasonable level of confidence in the reliability bound, quantitative tests usually require many more test cases than qualitative tests. The minimum number of test cases that must be executed is a function of the desired reliability threshold and the desired level of confidence. Following Brenner, Atkinson, Malaka, Merdes, Paech, and Suliman (2007) the number of required test cases can be calculated based on the given values for failure rate and confidence. The failure rate f for each operation was already specified earlier in the extra-functional requirements (Section 0). For the bid() operation the failure rate is $f = 0.002$.

In order to calculate the minimum number of test cases, the confidence in the test result is needed. Clearly, only one test case could be run and if no error is detected with this test case, the failure rate is said to be 0 and, thus, better than required. But the confidence in this test result cannot be high. On the other hand, it is obvious that to obtain higher confidence, the more test cases need to be run. In our example we assume a target confidence (c) of 95%.

When the number of test cases, n, is greater than 100 the calculation can be simplified. Then the Poisson distribution can be assumed and the term $\ln(1 - c)$ can be looked up in a table containing the values for the parameter a of the Poisson distribution. For $c = 0.95$, this is approximately $a = 3$, implying that during the test case execution no errors occur. So,

$$n = a / f = 3 / 0.002 = 1500$$

This means that 1500 test cases need to run without an error before we can be 95% sure that the failure rate of the bid() operation is smaller or equal to 0.002. If we accept one error during the test case execution, the minimum number of test cases required to hold the assumptions f = 0.002 and c = 0.95 raises to 2,400 (= 4.8 / 0.002). This provides an estimate for the required numbers of test cases.

RELATED WORK

The idea of testing services at run-time to determine if they are acceptable is related to the notion of quality of service. Several approaches for building Web services focus on QoS, such as availability, security, and throughput (Menasce, 2002). Typically, a global model of the interactions is created which is then evaluated so that adaptation strategies can be defined (Porter & Katz, 2006). However, the creation of such a global model takes a lot of effort and in dynamic contexts, such as Web services, it will change very quickly. Menasce, Ruan, and Gomaa (2004) propose an architecture where the server monitors its own quality and adapts accordingly. Our proposed approach differs from these approaches in that it focuses on functional qualities, that is, on whether the functionality provided by the service fits to the functionality required by the service consumer. This question is often considered as part of service matching. However, as always with software, additional testing is needed to uncover defects.

Numerous component-based development approaches have also developed techniques for enhancing systems testability using metadata provided by the component supplier, such as component behaviour specification, test cases together with coverage data, quality of service information, as well as specific information on code such as dependencies between variables (Orso, Harrold, & Rosenblum, 2000). This information is provided, for example, in the form of testable beans which comprise a testing interface and a traceability interface (Gao, Tsao, & Wu, 2003). The former enables the test to be set up, executed, and evaluated. The latter enables access to the history of test results. The wrapper approach separates the code for the metadata clearly from original code (Edwards, 2001). The notion of built-in tests enhances the testing interface with test cases (Gross, 2005). The test cases can be applied to the provided interface of the component (self-test) (Wang, King, Patel, Patel, & Dorling, 1999), or to the interface of its server components (contract test). This idea has been adapted to Web services where the service provider provides test cases for the service which can be applied by the service consumer to the service (Bruno, Canfora, DiPenta, Esposito, & Mazza, 2005).

Today, the main challenge of testing is still to define a test strategy which minimizes the relationship between test costs and defect costs. Such a strategy comprises a test focus (what should be minimized through the test), the test intensity (how much test effort should be spent on each risk), the test plan (who tests what), the test case definition method, the test case order, the test end criteria (when to stop testing), and the reaction to the test result (Borner, Illes, & Paech, 2007).

In component- and service-oriented systems, the main risk is a misunderstanding between the service and its clients. These risks are integration test risks, and can be classified according to typical defects. Wu, Pan, and Chen (2001) use such defects classification together with a global component interaction model to derive the test cases. Similarly, architecture-based approaches like that of Bertolino, Corradini, Inverardi, and Muccin (2000) and Muccini, Bertolino, and Inverardi (2004) use a global interaction model. As mentioned above, such global models are costly and, thus, it is important to identify typical defects of component interactions from the viewpoint of individual components.

The test cases can either be defined by hand, generated from models, or generated from the test history. Smythe (2006) discusses generation from models at development time. Run-time generation would save space, but requires an execution. In our method we do not give specific support for run-time generation. This is still a question for further research.

Another issue is *when* test cases are executed at run-time. Web service quality assurance approaches so far concentrate on run-time tests triggered and evaluated by humans, for example, after a new service is released. However, this will not be sufficient for a true service-oriented architecture where client-service relationships change very often. Merdes, Malaka, Suliman, Paech, Brenner, and Atkinson (2006) show how tests can be triggered and evaluated by the components themselves. This requires specific testing times and test reactions.

Obviously, the run-time test strategy will always be based on heuristics. Therefore, it is important to monitor and evaluate the test execution. This topic is still in its infancy, even for development-time testing. For run-time tests, evaluation strategies such as mutation test (Delamaro, Maldonado, & Mathur, 2001) and benchmarks (Zhu, Gorton, Liu, & Bui, 2006) need to be adopted. It is necessary to distinguish the quality of individual services as well as of the overall system (where the test strategies of several services interact). So far, our method does not provide specific support for this evaluation.

SUMMARY AND CONCLUSION

We have a presented a method for maximizing the testability of services by systematically ensuring that all information in their model-based specifications are included in their interfaces. As explained, there are numerous other approaches for designing tests of Web services based on their published interfaces, but these all "start" *after* the published interface has been fixed and encoded in a WSDL document or something similar. The novelty of the approach outlined in this chapter is that it addresses the problem of testability *before* the precise interface of the component has been fixed. In fact, it works by extending the basic functional interface beyond what it would normally be in normal methods.

The methodology exploits the fact that complex services are systems which are (or should be) designed using a systematic process of specification, realization, and implementation. More specifically, it exploits the fact that not all the information in the specification of a service (and thus in the contract) takes the form of operations that are accessible at run-time by clients. Semantic information such as externally visible states and attributes are often encapsulated within the body of service implementation, where they are accessible to development-time tests but not third-party client tests at run-time.

Since the main contribution of the approach is how to construct the concrete (i.e., WSDL) interface of a service rather than how to use them, it is compatible with most other approaches to service testing. In fact, we believe it naturally complements them. As part of the MORABIT project (2007), we have developed a prototype infrastructure to directly implement the kind of run-time tests supported in the approach and are currently in the process of building a tool to support the view-based specification of services upon which it is based.

ABSTRACT

Accessibility is the possibility of any person to make use of all the benefits of society, including the Internet. As the interfaces are typically graphic, sites can be an obstacle for visually impaired persons to access. For a site to be accessible to blind persons it's necessary the information contained in the visual resources be reproduced by means of an "equivalent" textual description, capable of transmitting the same information as the visual resources. This study is aimed at identifying and defining usability guidance compliant with accessibility W3C directives that can facilitate the interaction between visually impaired and Internet and still guarantee sites with understandable navigation content. Towards this end an exploratory study was conducted, comprised of a field study and interviews with visually disabled people from Instituto Benjamin Constant, reference center in Brazil for the education of visually impaired persons, in order to get to know these users better.

DOI: 10.4018/978-1-60566-386-9.ch014

INTRODUCTION

Accessibility is the term used to indicate the possibility of any person to make use of all the benefits of society, among which, the use of the Internet. (Nicholl, 2001). Digital accessibility is more specific and refers only to access to computer resources; accessibility to the Internet is the right to use the resources in the worldwide computer Web and accessibility to the Web, or *e-accessibility*, referring specifically to the Web component (Sales, 2003).

The Web component plays a fundamental role in the innovation that the Internet represents in the daily lives of persons with special needs; it facilitates the lives of these people as it allows them to create new ways of relating to others and performing activities previously unattainable (Takagi, 2004) and (Petrie, 2006). But getting digital accessibility is no simple matter; it requires organizations to adapt their resources in order to make the use of the computer accessible to any person (http_1).

In order to be accessed by visually impaired users, the graphic interface of computer systems should be designed with an "equivalent" textual description. These "equivalent" interfaces should be built in such a way that when accessed by support technology, they continue to provide "friendly" interaction, i.e., an interaction focused on usability. Hence, the present study is aimed at identifying and defining usability guidance compliant with accessibility laws, which may facilitate the interaction between those visually impaired and the Web, guaranteeing sites with understandable navigation content. This research is focused on Brazil`s necessities. To achieve this end, a Field work was conducted at the Instituto Benjamin Constant (IBC), an agency of the Ministry of Education of Brazil, and a center of excellence and national reference in matters related to studies of visual impairment (http_6

ACCESSIBILITY TO THE WEB OR E-ACCESSIBILITY

Digital accessibility refers to access to any Information Technology resource, whereas the term accessibility to the Internet is used, widely speaking, to define universal access to all components of the worldwide computer Web, such as chats, e-mail, and so on. The term Web accessibility, or *e-accessibility*, specifically refers to the Web component, which is a set of pages written in HTML language and interconnected by links to the hypertext (Sales, 2003), (Modelo, 2005) and (Nevile, 2005).

Aimed at making the Web accessible to all, W3C (the World Wide Web Consortium), an international committee that regulates matters linked to the Internet, created, in 1999, the WAI (Web Accessibility Initiative), made up of work groups intent on producing guidance to guarantee Web content accessibility to people with disabilities and to people accessing the Web under special conditions related to environment, equipment, navigator and other Web tools (Nevile, 2005), (http_5) and (Enap, 2007).

The members of W3C/WAI put together "W3C Accessibility Guidelines" (WCAG 1.0); this document is the first version for Accessibility to Web Content, released in May 1999, and has been the main reference to Web accessibility until today (http_5). In Brazil, accessibility began to be a part of public policy in the year 2000, when Federal Laws no. 10,048 dated November 8 2000, prioritizing services rendered to people with special needs, and no. 10,098 dated December 19 2000, establishing norms and criteria to guarantee accessibility were promulgated (Enap, 2007). In December 2004 these laws were regulated by decree no. 5,296 that initially established a 12-month deadline for all public administration or public interest sites to undergo an accessibility process; this deadline was subject to prorogation (Queiroz, 2007).

In order to define accessibility guidance at all levels, from physical to virtual spaces, ABNT's CB-40 Committee was put in charge of comparing accessibility norms in various countries and analyzing the guidelines proposed by W3C. As a result, a Brazilian Accessibility Model was designed (e-MAG) so as to generate a set of recommendations that could standardize and harmonize the accessibility process for Brazilian Government sites, enabling easy installation, thereby coherent with Brazilian needs and in conformity with international standards (Model, 2005) and (http_1).

Importance of Internet and Web Accessibility for those with Visual Impairment

The Web plays a fundamental role in the innovation that the Internet represents in the daily lives of those with visual impairment, making their lives easier; it allows them to establish new relationships, find job opportunities and forms of entertainment (Petrie, 2006) and (Queiroz, 2007).

Upon accessing a site, a user with normal eyesight uses a Browser. However, a blind or partially sighted person accessing the Internet would require support technology connected to the Browser, consisting of software called "screen readers", associated to other programs called "voice synthesizers".

Though important, digital accessibility is no simple matter. People with disabilities have sensorial and motor limitations which must be compensated for, one way or another, so as to enable their access to computer resources. With this in mind, organizations need to adapt their systems so that one single computer can be used by any person whatsoever (Harrison, 2005). The problem is that this adaptation requires technical expertise and specialized help, and this is why organizations very often do not make the needed effort to introduce accessibility procedures.

Levels of Accessibility

W3C Accessibility Guidelines (WCAG 1.0) proposed a set of fourteen directives for the Accessibility of Web Content. These directives deal with two generic themes: assure that the sites are accessible in a harmonious way and produce sites with understandable navigational content (http_5). WAI defined verification points for directives; each verification point was attributed a priority level, based on accessibility impact. Three levels of accessibility were defined; the Brazilian model also adopted these same priority levels (Model, 2005).

- **Priority level 1:** Norms and requirements related to verification points that Web designers must comply with so as not to make access unattainable to any group of users.
- **Priority level 2:** Norms and requirements related to verification points that Web designers must comply with so as not to hinder the access of any group of users.
- **Priority level 3:** Norms and recommendations that Web designers can comply with so as not to hinder access to saved files.

Programs for Accessibility Evaluation

Based on W3C/WAI recommendations, programs were designed to evaluate the level of accessibility to the site. These programs detect the HTML code and analyze content, verifying whether it is in compliance with the established set of rules or not; finally, they write reports listing the problems that need to be addressed for the site to be considered accessible (Spelta, 2003).

Some of this software is worth highlighting: *Bobby* (designed by the "Watchfire Corporation"), and *Lift* (designed by "Usablenet"). In Brazil, the *daSilva* program was designed to evaluate sites according to the rules established by WCAG and by e-MAG (http_4). This program was designed by "*Acessibilidade Brasil*", a "Public Interest Corporation" (OSCIP), whose mission is to develop studies for the social and economic insertion of people with impairments (http_1).

METHODOLOGY

The study, exploratory in nature, was carried out in three stages: (*a*) selection of the category of users; (*b*) bibliographic and documental research; (*c*) field work. These stages were accomplished concurrently.

The research work aimed at identifying and defining usability directives that are aligned with accessibility laws and which of these might facilitate the interaction between those visually impaired and the Internet, as well as guaranteeing sites with understandable navigation content.

Stages

a. **Selecting the category of users:** Users with visual impairment were chosen as the object of study of the present work; this decision was made based on the fact that the Internet has done much to contribute to improving the quality of life of those visually impaired, allowing them not only access to information that was previously only attainable with the help of another person, but also providing them with other facilities (Harrison, 2005).

b. **Biographical and documental research**: initially, we sought to understand the principles of accessibility and its implications for Internet sites. During this stage, some institutions provided different software destined for visually impaired users. This software was used to navigate in "common" sites, such as newspapers, and make a deeper observation and analysis of the various aspects brought up in the literature.

c. **Field work**: Field work was conducted at the Instituto Benjamin Constant (IBC), an agency of the Ministry of Education, founded in Rio de Janeiro in 1854 under the name of *Imperial Instituto dos Meninos Cegos*. IBC has become a center of excellence and national reference in matters related to studies of visual impairment. Its main aim is to promote the education and integration of visually impaired persons within a greater framework (http_6). During the field work, which took three months, different sectors of the institute were observed. In addition, several informal interviews and six in-depth interviews were conducted with employees, students and former students at the institution, most of whom are visually impaired and work there nowadays.

MODELS

Mental models are representations existing in the minds of people, which are used to explain, simulate, predict or control objects in the world. These representations are externalized through conceptual models. The elaboration of a user's conceptual model depends on the previous knowledge and experience of each person and is based on the expectations, aims and understanding of the user with regard to the system. Users create models based on "objects" they already know from their daily activities; they try to relate the computer elements to these familiar "objects", in an attempt to understand the machine better (Pressman, 2004).

As the perception of the system is influenced by the experiences of a person, each user creates his/her own conceptual model; since it is highly unlikely that people without special needs undergo similar experiences when surfing the Web as those with deficiencies, the models for disabled people tend to be distinct from the models for non-disabled people (Takagi, 2004). For example, according to Prof. Hercen, who was born blind, the window metaphor (Windows), which indicates the visualization of a work area, has no such meaning for a blind person (Hildebrandt, 2005).

When accessing a system, disabled users make use of a very different environment from non-disabled people. They relate the computer elements to "objects" from their day to day lives, developed to supply their needs. In addition, people with disabilities, such as blind persons, develop special skills, *e.g.*, excellent hearing; they hardly ever sit passively waiting to hear a spoken exit; they move around Web pages using complex combinations of keys. By means of this process, they create their own models and attempt to surf Web pages in a logical way. As these facts increase the level of difficulty when interacting with sites (Hanson, 2004), this ends up influencing their conceptual models (Takagi, 2004).

In systems geared to usability, the perception the user has of the system should be the closest possible to the system *per se*. This is why the designer should know the final users well enough to understand how they perceive the system, *i.e.*, their conceptual models. Thus when dealing with impaired users, it becomes essential to identify what types of impositions and limits they are subject to, in order to understand better their needs and special abilities (Takagi, 2004); an attempt should be made to understand all the hurdles users need to overcome to access information. If these hurdles are understood, it becomes possible to design easy-to-use interfaces for people with special needs as well (Harrison, 2005). The field work for the present study was conducted with this goal in mind.

VISUALLY IMPAIRED-MACHINE INTERACTION

The interface, graphic or otherwise, is the part of the software that users use to communicate with the system in order to perform their tasks; it should be designed to meet the users' expectations, allowing them to direct their attention to the objects they work with, which in turn reflect the real world (Pressman, 2004).

The interface should allow for user-friendly interaction; its design should be aimed at usability, the characteristic that determines whether the handling of a *product* is easy and quickly learned, difficult to forget, does not provoke operational errors, satisfies its users and efficiently resolves the tasks for which it was designed (Ferreira, 2003) and (Nielsen, 2002). If usability guides the system, users feel comfortable and encouraged to make use of it (Shneiderman, 2004). In order to build systems with sound usability, it is important that they be centered on the user (Norman, 1999); towards this end, one should get to know the final users, know how they perform their tasks, and the types of impositions and limits that they are subject to. Because graphic interfaces are a hurdle for visually challenged users, they must interact with the system using support technology capable of capturing interfaces and making them accessible.

USABILITY

Only recently the matter of usability has been perceived as important to information systems professionals. Driven by the market, organizations are going online in order to position themselves on a new way of performing business. Since the technology infrastructure used to construct Web sites can deal with images, sounds and text composition, it became more evident that the output of information should be treated with care (Ferreira, 2003).

Information system must be designed with the purpose of establishing a productive interaction between the system and their users in order to increase people's productivity while performing their tasks. They must satisfy the expectations and needs of their users. To achieve this end, the NFR (non functional requirement) usability must be present in any method for systems construction.

The communication between users and an Information System (IS) is established by means of the IS interface. A good IS design must guarantee a transparent communication, that is, it must assure that when a user accesses the IS to perform any task, he or she needs only to focus their energy on the intended task (Norman, 1986), (Norman, 1999) & (Jokela, 2004), (Seffah, 2004).

To have users focusing their attention mainly on their tasks, the process of software development must be "user centered", that is, its interface must be designed with the objective of satisfying the expectations and needs of users. The design of an interface that considers user characteristics and the NFR usability is a difficult process for many reasons, but most of this difficulty can be traced to the lack of attention on NFRs during the system definition process. Building systems that take in consideration NFRs, require the availability of a corpus of knowledge to help the engineer in the task of defining the system to comply with those requirements.

Usability Directives Focused on Accessibility

A usability oriented site is not necessarily accessibility oriented, and *vice versa*; a page may be easy to use for ordinary users, but inaccessible for those with special needs (Hanson, 2004). The directives recommend that site administrators check accessibility by accessing them through a screen reader; the problem is that those visually disabled, besides having special abilities, also use certain combinations of keys that a non-disabled person would not be able to simulate; hence, usability aspects differ from one user profile to that of another.

The authors of the current study agree that accessibility should be verified through a screen reader but that in order to obtain a universal access site geared to usability, it is essential that the difficulties and abilities of users be modeled as well, as these guide the mental model of their interactions. With such modeling, it would be possible to obtain usability directives that, in conjunction with the W3C accessibility directives, would provide for harmonious interaction of those disabled while guaranteeing understandable navigation sites.

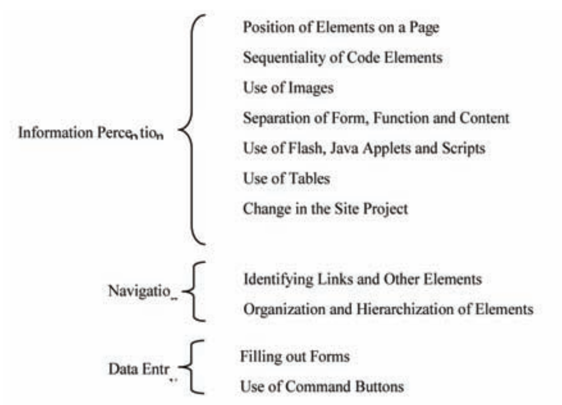
Usability issues occur, generally speaking, due to three reasons: the main aim of accessibility evaluation programs is compliance with directives where usability aspects are overlooked; many evaluation programs rely only on syntax verification techniques for sites and so detectable errors are limited to the tag description layer where the users' mental models are not taken into account (Takagi, 2004).

The literature (Ferreira, 2003), (Pressman, 2004) groups human-machine interaction sequences under two categories: *information visualization* and *data entry.* Based on the field work conducted at the *Instituto Benjamin Constant*, the present study proposes that, in interactions between visually impaired humans and machines, these sequences be grouped under three categories: *information perception*, *navigation* and *data entry.* After observing these interactions it was possible to identify certain usability directives, shown in the following sections (Figure 1).

Information Perception

Users accessing the Web by means of screen readers do not need to listen to all the words contained on the page: they only need to hear enough to determine where they want to go from there. It is, therefore, important that the interfaces be simple, because screen readers process the contents of a site differently from a visual reading process; to use them requires training and experience. Screen readers capture the HTML code, analyze the code and line up elements in the same order they appear in the code. As a result, visually impaired users perceive the page as if it were a text that they can

Figure 1. Usability directives



read line by line (by means of arrows) or link by link (by means of the tab key) (Nevile,2005).

Position of Elements on a Page

The order in which a screen element appears to the user accessing a page by voice reader is not the same order in which it appears visually on a navigator. What determines when it appears on the screen reader is the position it holds in the source code. An important element may very often have a prominent position on the page shown on a navigator, but when analyzed by the screen reader, ends up being one of the last elements users notice, as it is positioned at the end of the code. Aside from losing its prominent position, it will be perceived only after a number of less important information appears (Hildebrandt, 2005).

Sequentiality of Code Elements

Sequentiality is one of the barriers found by those visually disabled when browsing a site with a screen reader (or by means of a program that amplifies the interface): the user is only able to access a limited portion of the screen and, thus, loses out on the idea of the general context of the page at hand (Leporini, 2004). This is why HTML language tags that can be identified by the screen reader become an important element in the information perception process of visually impaired users. They allow the reader to provide information about the structure of the site (Leporini, 2004).

Hence, when designing an interface to be accessed by visually impaired users, one should be careful since many visual characteristics, such as bold, underline, italics, font styles, etc. are not detectable to the reader and so become imperceptible; on the other hand, other invisible elements, such as labels, link titles and alt attributes for images can be used to highlight information (Leporini, 2004).

Use of Images

The W3C 1.1 directive states that all non-textual information must be accompanied by a text. It is recommended that the alt attribute should always be present so that contents can be read by a screen reader. The alt attribute (alternate text) provides an alternative text associated to an image; in most navigators, the alt textual content is shown to the ordinary user when the mouse passes over the image. When the mouse moves away from the image, this window disappears. Likewise, when the page is being downloaded and an image is still being downloaded, the block with the alt text content appears until the final figure is shown.

If the texts for these image attributes are written appropriately, they can provide useful information for disabled users with respect to the meaning of the images being read by the screen readers (Queiroz, 2007), (Hanson, 2004) and (Harrison, 2005).

When a site contains an image without an alt attribute, this image may be detected or not; it will depend on the screen reader program being used. Some readers don't pick up anything, while others may indicate the existence of an "image" to the visually impaired user, but cannot furnish any information about the nature of the figure (Queiroz, 2007).

For instance, an interviewee reported not being able to register with an Internet provider as the link was hidden, probably because it was represented by an image without alt attribute. In her opinion the descriptive text of an image is only useful if it brings relevant information not available in the text (Livramento, 2005).

Interviewees say they prefer texts without images. What is more, they also state they cannot often find subtitles that might justify the presence of the image on the page. Perhaps bad use of alt attributes is in part responsible for the rejection of images, found to be the case in the current research work (Hildebrandt, 2005; Coube, 2005) (Livramento, 2005).

Separation of Form, Function and Content

Although a union of form, function and content are essential to obtain a complete and accessible site, the intersection between these elements may result in inconsistencies among different navigators or even among distinct means of access, as PDAs and cell phones. One should separate these elements, restricting the use of HTML to a description of the content and the use of CSS (Cascading Style Sheets) to the formatting (http_5).

As it offers many more resources for formatting and a more precise control for exhibiting each element in comparison with HTML formatting tags, the CSS standard plays an important role in Web accessibility. When using only CSS to format a page, the HTML code is restricted to the function of gathering and ranking the content, thus enabling navigators that do not depend on formatting – as is the case of screen readers for the visually impaired – to ignore the CSS code and concentrate only on what is contained in the HTML.

Use of Flash, Java Applets and Scripts

As HTML is not a programming language, in order to make sites more interesting, solutions were found to allow them to contain programs. Among these solutions, one can find scripts, small programs incorporated in Web pages with a capacity to generate special animated effects, formatting and forms.

As time passed, more powerful technology, like Flash and Java, began to be used to animate sites, and to make them interactive and more attractive. However, most flash and java applet files cannot be deciphered by screen readers. Though recent versions of Flash include resources that enable integration with accessibility support mechanisms, there are still limits to the relationship between flash components and text navigators, as is the case of certain screen readers. One solution would be to create a link for a text version without these resources (Queiroz, 2007).

Use of Tables

When a screen reader is used, tables are read horizontally, line by line. As visually impaired users cannot visualize the whole table and so have to rely on their memory to know in which position different columns are to be found, it would be preferable to re-read the heading of each column (the first cell of each column) before reading the data contained in each cell (Livramento, 2005). HTML offers resources that allow distinguishing the heading of the remaining cells, paving the way for this type of reading, as long as this distinction is correctly applied in the font code. It is, therefore, good usability practice to identify the names of each column and line by means of the “th” tag (table header).

Change in the Site Project

There are two types of alterations that can be made in sites. The first and more frequent one consists of simply updating the content without modifying the page layout. Newspapers, for example, are updated continually. This does not cause any uneasiness for visually impaired users.

The second and more problematic one occurs when the project of the site is altered. This obliges the visually impaired user to relearn the name and position of all the key elements on the page. Though this was not considered an obstacle, the visually impaired interviewees (Coube, 2005), (Hildebrandt, 2005) and (Livramento, 2005) wished to be notified every time a new version of the site came into effect. One interviewee reported that, when the page of her provider was modified, she and her husband, also blind, had no idea what was going on, unsure of whether it was an error on the part of the program or something they had done wrong (Livramento, 2005). One suggestion to cater to the needs of the visually impaired user is to put some identification inside the page containing the number and date of the current version.

Navigation

Visually disabled users do not use the mouse to navigate, since this device requires visual coordination (aim) (Queiroz, 2007). They mainly use the tab key and combinations of keys, called *shortcut keys*. These keys can also be used by non-disabled users to expedite certain tasks (Leporini, 2004). Using these keys requires learning one more skill, which leads partially sighted users to prefer using their residual sight (Hanson, 2004). This is why one should select a background color that will create a contrast between the background and the text to facilitate reading (Hanson, 2004).

Identifying Links and Other Elements

When navigating by means of keys, it is essential that the text describing the link be identified in an informative and useful way (Harrison, 2004); this text will be picked up by the screen reader and it is by this means that the disabled user will know what the link is for. So, simply identifying links with words like "click here" or "next" are an obstacle for users who rely on voice readers, as is the case of the visually impaired (http_1).

Organization and Hierarchization of Elements

Screen readers provide functions that enable users to jump directly to the various heading tags, a key element in structuring easy-to-navigate sites. By means of a tag, visually impaired users can navigate using the titles so as to get a general idea of the page (Takagi, 2004).

According to Livramento (2005), sites structured as paragraphs provide more objective navigation. Visually impaired users like to have the option of navigating by jumping from one paragraph to another, only reading through the ones they consider important; experienced users are quickly able to identify if they wish to continue reading a paragraph or skip to another, in this way approximating their method of reading to that of a person with ordinary eyesight (Livramento, 2005).

This is why it is essential to adopt the practice of signaling each paragraph in HTML code by means of a "p" tag instead of a "br" tag, which only enables a line break.

One of the problems in using a screen reader is that navigation on links is sequential (Leporini, 2004). This can slow down navigation. For instance, to return to a link to one's left, one would have to jump over all the links in order to restart reading the page and finally arrive at the desired content. Sites should provide resources that would enable users to jump links repeatedly, accelerating interaction. Hence skip links should be used, speeding up navigation and allowing users to jump links repeatedly and go directly to the desired content (Harrison, 2004). Skip links are not noticeable when a site is exhibited on an ordinary navigator, and are only useful when the site is being accessed by a screen reader (Takagi, 2004).

Data Entry

On entering data, visually impaired users do not use the mouse, but the keyboard, which has become a facilitator capable of being used by any visually disabled user due to an international typing norm: all keyboards produced in conformity with regional technical norms have, on the lower part of the J and F keys (on the alphanumerical side) and 5 (on the numerical side), high-relief to guide blind people when positioning their hands, just as people do when learning to type (Queiroz, 2007).

Relying solely on the keyboard, one could spend a long time choosing commands, typing data and inputting other things. Added measures should be taken to promote accessibility in interfaces dealing with data entry (Ferreira, 2003).

Filling Out Forms

If filling out forms can be a constraint for just any user, it is much worse for those visually impaired, forcing them at times to abandon the site. The simple fact that many sites have restricted access requiring passwords, which, due to security reasons are not spelled out by screen readers, already hinders user access.

One way people send data over the Internet is by filling out forms. Since the user navigates through forms by using the tab key, in order to facilitate data entry, the fields to be filled out and search buttons, if important, should preferentially be located at the top of the page. (Leporini, 2004).

Some interfaces are made in such a way that very often, when a visually impaired user locates the field to be filled out, no voice indication is made to explain what needs to be done; the user only hears a standard notification from the reader: “edit box.” The “label” tag would allow placing a text to be read by the user, giving information on what needs to be filled out (Queiroz, 2007). This tag also permits attributing a rapid access key to each field on the form, in addition to enlarging the click field for *selection box* and *radio box*, which would make filling out forms easier for those with only partial visual impairment. One should also avoid using a default value in the field, because even when read by the reader, it would require the user to erase the value (Harrison, 2004).

Another error found in forms is the indication of fields where one is required to make use of different color or font formatting. An alternative to this would be to use an asterisk, but screen reader users often disable the punctuation. Ideally this should be indicated by a letter that would represent the word “obligatory” (Harrison, 2004).

Use of Command Buttons

Another way of sending data is by means of command buttons, such as the “send” or “submit” button; these do not require a “label,” since they can be read by means of the “value” attribute; however, one should avoid using words such as “click here” or “continue” with this attribute, because they indicate nothing about the purpose of the button. If the button has an image instead of a text, it would suffice to use the “alt” attribute (Queiroz, 2007).

CONCLUSION

The current paper was motivated by the law decreed and signed in December 2004 that defined a twelve-month deadline for accessibility of public sites. Many organizations were prompted to try to adapt their information systems as a result of this decree in an attempt to obtain the accessibility certification.

Concern over accessibility at the moment of designing or redesigning a site does not guarantee this accessibility is maintained later when the site is updated. Constant and continual verification of accessibility should be made in order to avoid modifications in content or structure that would compromise the initial accessibility of the project. A new challenge emerges: that of designing, administering and maintaining sites in conformity with accessibility directives that are not only current and easy but also attractive.

Field research was conducted at the Instituto Benjamin Constant, the main reference center in Brazil for the education and re-education of those visually impaired, in order to get to know visually disabled users better. The reason for choosing visually disabled people was the fact that the Internet has done much to contribute to the improvement in the quality of their lives, allowing them to engage in new forms of relationships, find work opportunities and alternate forms of entertainment. This research work has prompted the understanding of how these users perceive and interact with sites and has identified certain hurdles that they need to overcome in order to access information. Through the understanding acquired in the field work and based on the literature, different types of impositions and limits that these users are subject to have been identified, enabling a better perception of their needs and special abilities. As a result, impaired user-machine interaction sequences have been grouped together into three categories: *information perception*, *navigation* and *data entry*. These interactions were observed and analyzed, which enabled the identification of certain usability directives that could contribute to the accessibility of sites in alignment with W3C directives, with emphasis on facilitating visually impaired user access to the Web.

KEY TERMS AND DEFINITIONS

Accessibility: Term used to indicate the possibility of any person to make use of all the benefits of society.

Usability: Term used to denote the ease with which people can employ a particular tool or other human-made object in order to achieve a particular goal.

Visually Impaired: Vision loss that constitutes a significant limitation of visual capability resulting from disease, trauma, or a congenital or degenerative condition that cannot be corrected by conventional means, including refractive correction, medication, or surgery.

Instituto Benjamin Constant (IBC): Center of excellence and national reference in matters related to studies of visual impairment.

World Wide Web Consortium (W3C): The main international standards organization for the World Wide Web (abbreviated WWW or W3).

Web Accessibility Initiative (WAI): An effort to improve the accessibility of the World Wide Web (WWW or Web) for people using a wide range of user agent devices, not just standard Web browsers. This is especially important for people with physical disabilities which require such devices to access the Web.

Chapter 8.9
Web Application Server Clustering with Distributed Java Virtual Machine[1]

King Tin Lam
The University of Hong Kong, Hong Kong

Cho-Li Wang
The University of Hong Kong, Hong Kong

ABSTRACT

Web application servers, being today's enterprise application backbone, have warranted a wealth of J2EE-based clustering technologies. Most of them however need complex configurations and excessive programming effort to retrofit applications for cluster-aware execution. This chapter proposes a clustering approach based on distributed Java virtual machine (DJVM). A DJVM is a collection of extended JVMs that enables parallel execution of a multithreaded Java application over a cluster. A DJVM achieves transparent clustering and resource virtualization, extolling the virtue of single-system-image (SSI). The authors evaluate this approach through porting Apache Tomcat to our JESSICA2 DJVM and identify scalability issues arising from fine-grain object sharing coupled with intensive synchronizations among distributed threads. By leveraging relaxed cache coherence protocols, we are able to conquer the scalability barriers and harness the power of our DJVM's global object space design to significantly outstrip existing clustering techniques for cache-centric web applications.

DOI: 10.4018/978-1-60566-661-7.ch028

INTRODUCTION

Scaling applications in web server environment is a fundamental requisite for continued growth of e-business, and is also a pressing challenge to most web architects when designing large-scale enterprise systems. Following the success of the Java 2 Platform, Enterprise Edition (J2EE), the J2EE world has developed an alphabet soup of APIs (JNDI, JMS, EJB, etc) that programmers would need to slurp down if they are to cluster their web applications. However, comprehending the bunch of these APIs and the clustering technologies shipped with J2EE server products is practically daunting for even those experienced programmers. Besides the extra configuration and setup time, intrusive application rework is usually required for the web applications to behave correctly in the cluster environment. Therefore, there is still much room for researchers to contribute improved clustering solutions for web applications.

In this chapter, we introduce a generic and easy-to-use web application server clustering approach coming out from the latest research in distributed Java virtual machines. A *Distributed Java Virtual Machine (DJVM)* fulfills the functions of a standard JVM in a distributed environment, such as clusters. It consists of a set of JVM instances spanning multiple cluster nodes that work cooperatively to support parallel execution of a multithreaded Java application. The Java threads created within one program can be distributed to different nodes and perform concurrently to exploit higher execution parallelism. The DJVM abstracts away the low-level clustering decisions and hides the physical boundaries across the cluster nodes from the application layer. All available resources in the distributed environment, such as memory, I/O and network bandwidth can be shared among distributed threads for solving more challenging problems. The design of DJVM adheres to the standard JVM specification, so ideally all applications that follow the original Java multithreaded programming model on a single machine can now be clustered across multiple servers in a virtually effortless manner.

In the past, various efforts have been conducted in extending JVM to support transparent and parallel execution of multithreaded Java programs on a cluster of computers. Among them, Hyperion (Antoniu et al., 2001) and Jackal (Veldema et al., 2001) compile multithreaded Java programs directly into distributed applications in native code, while Java/DSM (Yu & Cox, 1997), cJVM (Aridor, Factor, & Teperman, 1999), and JESSICA (Ma, Wang, & Lau, 2000) modify the underlying JVM kernel to support cluster-wide thread execution. These DJVM prototypes debut as proven parallel execution engines for high-performance scientific computing over the last few years. Nevertheless, their leverage to clustering real-life applications with commercial server workloads has not been well-studied.

We strive to bridge this gap by presenting our experience in porting the Apache Tomcat web application server on a DJVM called JESSICA2. A wide spectrum of web application benchmarks modeling stock quotes, online bookstore and SOAP-based B2B e-commerce are used to evaluate the clustering approach using DJVMs. We observe that the highly-threaded execution of Tomcat involves enormous fine-grain object accesses to Java collection classes such as hash tables all over the request handling cycles. This presents the key hurdles to scalability when the thread-safe object read/write operations and the associated synchronizations are performed in a cluster environment. To overcome this issue, we employ a home-based hybrid cache coherence protocol to support object sharing among the distributed threads. For cache-centric applications that cache hot and heavyweight web objects at the application-level, we find that by using JESSICA2, addition of nodes can grow application cache hits linearly, significantly outperforming the share-nothing approach using web server load balancing plug-in. This is attributed to our *global object space (GOS)* architecture that virtualizes network-wide memory resources for caching the application data as a unified dataset for global access by all threads. Clustering HTTP sessions over the GOS enables effortless cluster-wide session management and leads to a more balanced load distribution across servers than the traditional sticky-session request scheduling. Our coherence protocol also scales better than the session replication protocols adopted in existing Tomcat clustering. Hence, most of the benchmarked web applications show better or equivalent performance compared with the traditional clustering techniques.

Overall, the DJVM approach emerges as a more holistic, cost-effective and transparent clustering technology that disappears from the application programmer's point of view. With efficient protocol support for shared object access, such a middleware-level clustering solution is suitable for scaling most web applications in a cluster environment. Maturing of the DJVM technology would bring about stronger server resource integration and open up new vistas of clustering advances among the web community.

The rest of the chapter is organized as follows. In Section 2, we survey the existing web application clustering technologies. Section 3 presents the system architecture of our JESSICA2 DJVM. In Section 4, we describe Tomcat execution on top of the JESSICA2 DJVM. Section 5 discusses JESSICA2's global object space design and implementation. In Section 6, we evaluate the performance of Tomcat clustering using the DJVM. Section 7 reviews the related work. Section 8 concludes this chapter and suggests some possible future work.

EXISTING WEB APPLICATION CLUSTERING TECHNOLOGIES

In the web community, clustering is broadly viewed as server load balancing and failover. Here, we discuss several widely adopted clustering technologies under the hood of J2EE.

The most common and cost-effective way for load balancing is to employ a frontend web server with load balancing plug-ins such as Apache mod_jk (ASF, 2002) to dispatch incoming requests to different application servers. The plug-ins usually support *sticky-sessions* to maintain a user session entirely on one server. This solution could make the cluster resource utilization more restricted and is not robust against server failures.

More advanced solutions need to support application state sharing among servers. Large-scale J2EE server products generally ship with clustering support for HTTP sessions and stateful session beans. One traditional approach is to serialize the session contents and persist the states to a data store like a relational database or a shared file system. However, this approach is not scalable. *In-memory session replication* is an improved technique also based on Java serialization to marshal session-bound objects into byte streams for sending to peer servers by means of some group communication services such as JGroups (Ban, 1997) (based on point-to-point RMI or IP multicast). Such a technique has been implemented in common web containers such as Tomcat. However, scalability issues are still present in group-based synchronous replications, especially over the general all-to-all replication protocols which are only efficient in very small-size clusters.

Enterprise JavaBeans (EJB) is a server-side component architecture for building modular enterprise applications. Yet the EJB technology itself and its clustering are both complicated. Load balancing among EJB containers can be achieved by distributed method call, messaging or name services which correspond to the three specifications: Remote Method Invocation (RMI), Java Messaging Service (JMS) and Java Naming and Directory Interface (JNDI). In particular, JNDI is an indispensible element of EJB clustering as EJB access normally starts with a lookup of its home interface in the JNDI tree. For clients to look up clustered objects, EJB containers implement some global JNDI services (e.g. cluster-wide shared JNDI tree) and ship with special RMI compilers to generate *replica-aware stubs* for making user-defined EJBs "cluster-aware". The stub contains the list of accessible target EJB instances and codes for load balancing and failover among the instances. EJB state changes are serialized and replicated to peer servers after the related transaction commits or after each method invocation. Undoubtedly, this clustering technology is expensive, complicated and with application design restrictions.

In recent years, a growing trend in web application development has begun to adopt lightweight containers such as the Spring Framework (Johnson, 2002) to be the infrastructural backbone instead of the EJB technology. On such a paradigm, business objects are just *plain old Java objects* (POJOs) implementing data access logic and running in web containers like Tomcat. Caching POJOs in a collection object like Hashtable is also a common practice for saving long-latency access to database and file systems. To support clustering of POJOs which conform to no standard interface, it seems almost inevitable that application programmers have to rework their application code to use extra APIs to synchronize object replicas among the JVMs. Though distributed caching libraries (Perez, 2003) can facilitate POJO clustering, these solutions again rely on Java serializations and require complex configurations. The cache sizes they support are usually bounded by single-node memory capacity as a result of employing simplistic all-to-all synchronization and full replication protocols.

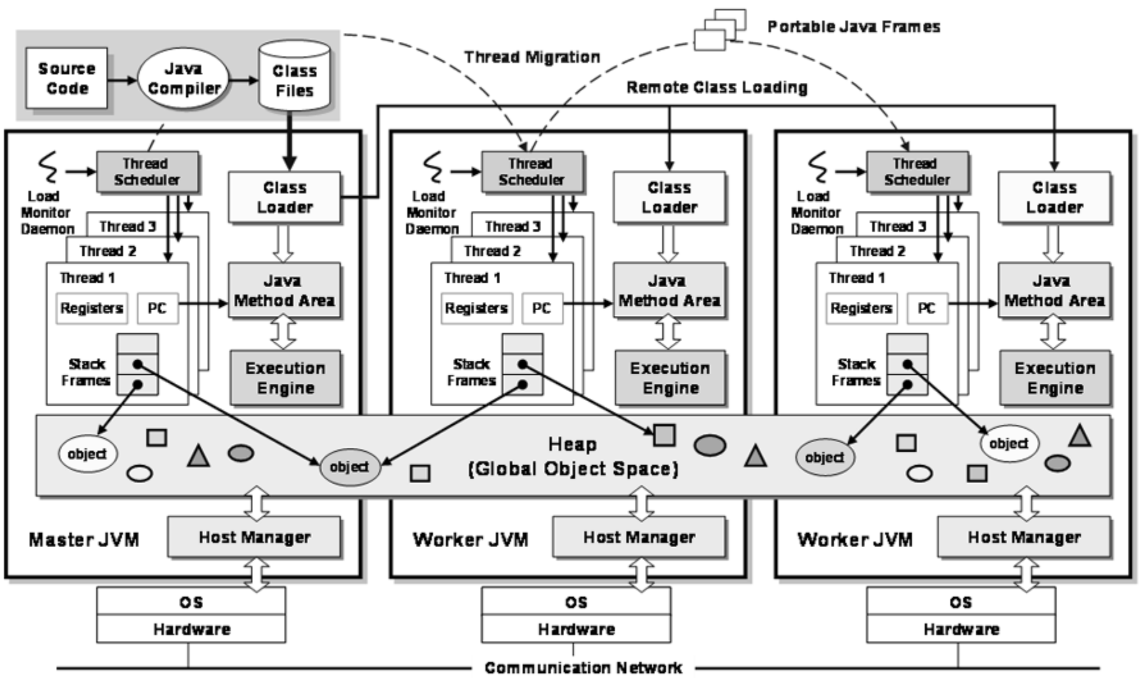
Although the clustering solutions surveyed so far have their own merit points, most of them share several significant shortcomings.

- **Restrictions on application design:** Many object sharing mechanisms rely on Java serializations which pose restrictions on application design and implementation. They cannot easily work in a cluster environment.
- **Possible loss of referential integrit**y: Most solutions suffer the break of referential integrity since it creates clones of the replicated object graph at deserialization and may lose the original object identity. That's why when a shared object undergoes changes, it must be put back into the container object by an explicit call like setAttribute() to reflect the new referential relation. Likewise, consistency problems occur when attributes with cross-references in HTTPSession are modified and unmarshaled separately.
- **Costly communication:** Object serialization is known to be hugely costly in performance. It performs a coarse trace and clones a lot of objects even for one field change. So there is certain limit on the number and sizes of objects that can be bound in a session.
- **No global signaling/coordination support:** Subtle consistency problems arise when some design patterns and services are migrated to clusters. For example, the *singleton pattern* sharing a single static instance among threads as well as some synchronization codes become localized to each server, losing global coordination. Event-based services like timers make no sense if they are not executed on a single platform. Only a few products (e.g. JBoss's clustered singleton facility) ship with configurable cluster-wide coordination support to ease these situations.
- **Lacking global resource sharing:** Most clustering solutions in the web domain put little focus on global integration of resources. They cannot provide a global view of the cluster resources such as memory, so each standalone server just does its own work without cooperation and may not fully exploit resources.

JESSICA2 DISTRIBUTED JVM

JESSICA2 (Zhu, Wang, & Lau, 2002) is a DJVM designed to support transparent parallel execution of multithreaded Java applications in a networked cluster environment. It was developed based on

Figure 1. JESSICA2 DJVM System Architecture



Kaffe JVM (Wilkinson, 1998). The acronym JESSICA2 spells as Java-Enabled Single-System-Image Computing Architecture version 2; this architecture promotes the *single-system image (SSI)* notion when connecting Java with clusters. Such a design concept is helpful to take away the burden of clustering by hand from application developers. The key advantage with using JESSICA2 is its provision of transparent clustering services which require no source code modification and bytecode preprocessing. It will automatically take care of thread distribution, data consistency of the shared objects and I/O redirection so that the program will run under an SSI illusion with integrated computing power, memory and I/O capacity of the cluster.

Figure 1 shows the system architecture of the JESSICA2 DJVM. JESSICA2 has bundled a number of salient features extended from the standard JVM that realize the SSI services. To execute a Java application on JESSICA2, a tailored command is called to start the master JVM on the local host and the worker JVMs on remote nodes, based on the specified list of hostnames. In each JVM, a class loader is responsible for importing bytecode data (of both the basic Java class library classes and the application classes) into its method area where a Java thread can look up a specific method to invoke. The class loader of JESSICA2 is extended to support *remote class loading* which ensures when a worker JVM cannot find a class file locally, it can request the class bytecode on demand and fetch the initialized static data from the master JVM through network communication. This feature greatly simplifies cluster-wide deployment of Java applications and hence transparently provides the *web farming* support which traditionally requires application server extension to fulfill.

When the Java threads of the application are started, the thread scheduler of the JVM will put their contexts (e.g. program counter and other register values) into the execution engine in turns. The Java methods invoked by the running thread will be compiled by the Just-In-Time (JIT) compiler into native codes for high-speed execution. JESSICA2 incorporates a cluster-aware JIT compiler to support lightweight *Java thread migration* across node boundaries to assist global thread scheduling. Java threads will be assigned to each worker JVM at the startup time in a round-robin manner to strike a raw load balance. Dynamic load balancing during runtime can be done by migrating Java threads that are running into computation hotspots to the less loaded nodes. For detecting hotspots, each JVM instance has a *load monitor* daemon that periodically wakes up and sends current load status such as CPU and memory utilization to the master JVM which is then able to make thread migration decisions with a global resource view.

Java threads migrated to remote JVMs may still be carrying references to the objects under the source JVM heaps. For seamless object visibility, JESSICA2 employs a special heap-level service called the *Global Object Space (GOS)* to support location-transparent object access. Objects can be shared among distributed threads over the GOS as if they were under a single JVM heap. For this to happen, the GOS implements object packing functions to transform object graphs into byte streams for shipping to the requesting nodes. The shipped object data will be saved as a *cache copy* under the local heap of the requesting node. Caching improves data access locality but leads to cache consistency issues. To tackle the problem of stale data, the GOS employs *release-consistent* memory models stemmed from software Distributed Shared Memory (DSM) systems to preserve correct memory views on shared objects across reads/writes done by distributed threads.

JESSICA2 offers parallel I/O and location-transparent file access. We extend JESSICA2 to support *transparent I/O redirection* mechanism so that I/O requests (file and socket access) can be virtually served at any node. Our system does not rely on shared distributed file systems such as NFS, nor does it need to restrict a single IP address for all the nodes in the running cluster. Rather, we extend each JVM to run a *transparent I/O redirection* mechanism to redirect non-home I/O operations on files or sockets to their home nodes. To attain I/O parallelism atop transparency, read-only file operations and connectionless network I/O can be done at the local nodes concurrently without redirection.

Finally, all inter-node communication activities required by the subsystems at upper layers like the GOS and I/O redirections are supported by a common module called the *host manager* which wraps up the underlying TCP communication functions with connection caching and message compression optimizations.

On the whole, we can see that DJVM is a rather generic middleware system that supports parallel execution of any Java program. Since the unveiling of DJVMs, their application domains remain mostly in scientific computing over the last few years. They were used to support multithreaded Java programs that are programmed in a data-parallel manner. These applications tend to be simple, embarrassingly parallel so that DJVMs could offer good scalability. However, much more mainstream applications are business-oriented, centered at server-side platforms and run atop some Java application servers. Their object access and synchronization patterns are far more complex. In the next sections, we will elaborate on the common runtime characteristics of application servers and their impacts on the DJVM performance through a case study of Apache Tomcat running on JESSICA2.

APACHE TOMCAT ON DISTRIBUTED JVM

Apache Tomcat is a Java servlet container developed at the Apache Software Foundation (ASF). It serves as the official reference implementation of the Java Servlet and JavaServer Page (JSP) specifications. Tomcat is the world's most widely used open-source servlet engine and has been used by renowned companies like WalMart, E*Trade Securities and The Weather Channel to power their large-scale and mission-critical web applications in production systems.

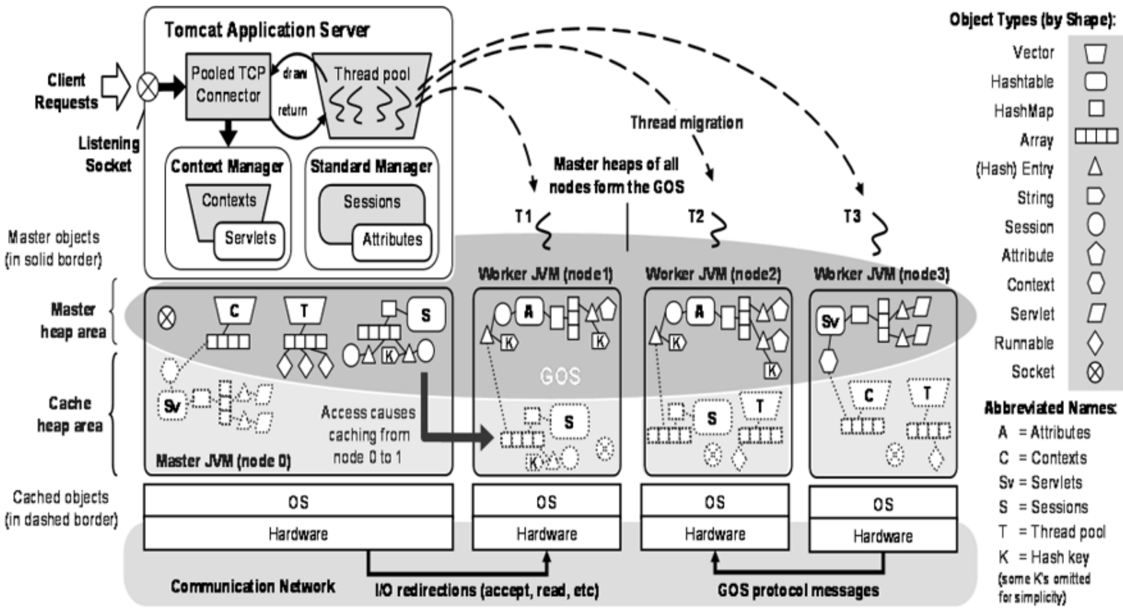
As a common design in many servers, Tomcat maintains a thread pool to avoid thread creation cost for every short-lived request as well as to give an upper bound to the overall system resource usage. Upon an incoming connection, a thread is scheduled from the pool to handle it. The web container then performs various processing such as HTTP header parsing, sessions handling, web context mapping and servlet class loading. The request eventually reaches the servlet code which implements application logics such as form data processing, database querying, HTML/XML page generation, etc. Finally, the response is sent back to the client. This request service cycle is complex, comes across many objects throughout the container hierarchy and imposes multithreading challenges to the DJVM runtime.

Being a classical and large-scale web application server, Tomcat reflects an important class of real-life object-oriented server execution patterns that are summarized as follows.

1. **I/O-intensive workload**: Most web server workloads are I/O-bound and composed of short-lived request processing. The per-request computation-communication ratio is usually small.
2. **Highly-threaded**: It is common that a server instance is configured with a large number of threads, typically a few tens to a hundred per server to hide I/O blocking latency.
3. **High read/write ratios**: Shaped by customer buying behaviors and e-business patterns, web applications usually consist of high read/write ratio, say around 90/10; the dominant reads come from browsing while only a few writes owing to ordering happen over a period.
4. **Long-running**: Typically a server application runs for an indefinitely long time, processing requests received from the client side.
5. **High utilization of collection framework**: Tomcat makes extensive use of Java collection classes like Hashtable and Vector to store information (e.g. web contexts, sessions, attributes, MIME types, status codes, etc). They are accessed frequently when checking, mapping and searching operations happen inside the container. To reduce object creation and garbage collection costs, many application servers apply the *object pooling* technique and use collection classes to implement the object pools.
6. **Fine-grain object access**: Fine-grain object access has two implications here: (1) the object size is small; (2) the interval between object accesses to the heap is short. Unlike many scientific applications which have well-structured objects with size of at least several hundred bytes, Tomcat contains an abundance of small-size objects (average about 80 bytes by our experience) throughout the container hierarchy. Object accesses are very frequent due to object-oriented design of Tomcat.
7. **Complex object graph with irregular reference locality**: Some design patterns such as facade and chain of interceptors used in Tomcat yield ramified object connectivity, cross-referencing and irregular reference locality among objects throughout the container hierarchy. By property 5, heavy use of Java Hashtable or HashMap also intensifies the irregularity of reference locality as hash entries are accessed in a shuffling pattern, contrasting with the consecutive memory access pattern in array-based scientific computations.

Figure 2 depicts the execution of the Tomcat application server on top of a 4-node cluster. When

Figure 2. Execution of Tomcat on JESSICA2 DJVM



Tomcat is executed atop JESSICA2, Tomcat is exposed to an SSI view of the integrated resources of the cluster nodes as if it was in one powerful server. A customized Tomcat startup script is used to bring up the server, running atop the master JVM. The script is tailored to supply the DJVM runtime parameters (e.g. the port number for master-worker handshaking) and to read a host configuration file which defines the hostnames or IP addresses of the worker nodes the DJVM would span.

When the server spawns a pool of threads, the threads will be migrated to the worker nodes. They will load the classes of the Java library, Tomcat and the web applications deployed dynamically through the cluster-aware class loader of JESSICA2. In this way, "virtual" web application server instances are set up on the worker nodes. The virtual server instances pull workload continuously from the master node by accepting and handling incoming connections through transparent I/O redirections. On each worker node, I/O operations (accept, read/write and close) performed on the shared server socket object (wrapped in the pooled TCP connector) will be redirected to the master node where it was bound to the outside world. Most other I/O operations can be performed on I/O objects created locally; so each cluster node can serve web page requests and database queries in parallel.

When a client request is accepted, the context manager of Tomcat will match it to the target web application context. If the request carries session state such as a cookie, the standard manager will search for the allocated session object from the sessions hash table. In essence, all Tomcat container objects including the context manager, the standard manager, the sessions hash table and web contexts allocated in the master JVM heap are transparently shared among the distributed threads by means of the underlying GOS service mentioned in section 3. When a thread gets the first access to a non-local object reference, it will encounter an *access fault* and send a fetching request to the object's home node. The home node will respond with the up-to-date object data and export the local object as the home copy of the shared object. Cluster-wide data consistency will be enforced on the home copy and all cache copies derived from it thereafter. Since each thread will be able to see the shared object updates made by others through synchronization, the global shared heap creates an *implicit cooperative caching effect* among the threads. The power of this effect can be exemplified by collection classes like hash tables.

As illustrated, all HTTP sessions stored in a Tomcat-managed hash table can be globally accessible. The responsibility of maintaining HTTP session data consistency across servers has transparently shifted to the GOS layer. In other words, every server is eligible to handle requests belonged to any client session. This leads to more freedom of choice in request scheduling policies over sticky-sessions load balancing which can run into hotspots. Another useful scenario is using the GOS to augment the effective cache size of an application-level in-memory Java cache (e.g., a hash table for looking up database query results). The fact that every thread sees the cache entries created by one another contributes to secondary (indirect) application cache hits through remote object access. The cache size can now scale linearly with additional nodes, so we can greatly take the load off the bottlenecked database tier by caching more data at the application tier.

The DJVM approach inherits most advantages of clusters. However, the aforesaid server runtime properties bring additional design challenges on the DJVM runtime. First, I/O intensive workloads are known to be more difficult to scale efficiently over a cluster. Second, the high thread count property implies higher blocking latency if contention occurs. More memory overheads would be resulted from any per-thread protocol data structures. High read/write ratio is a positive news to the GOS as it implies shared writes are limited, so our protocols can take this property as a design tradeoff. Next, for long-running applications, we need to make sure the memory overhead induced by the coherence protocol data structures scales up slowly for less frequent garbage-collection cycles. Property 5 puts up the biggest barrier to scalability. Frequent synchronizations on the globally shared thread pool and object pools produce intensive remote locking overhead. Worse still, these pools are usually built from Java collection classes which are not scalable. For example, fine-grain accesses to hash entries of a Java hash table are all bottlenecked around the single map-wide lock contention which will be much intensified by distributed locking. Finally, properties 6 and 7 together issue enormous remote access roundtrips and demand smart object prefetching techniques for aggregating fine-grain communications. These observations call for a renovation of JESSICA2's global object space (GOS) architecture.

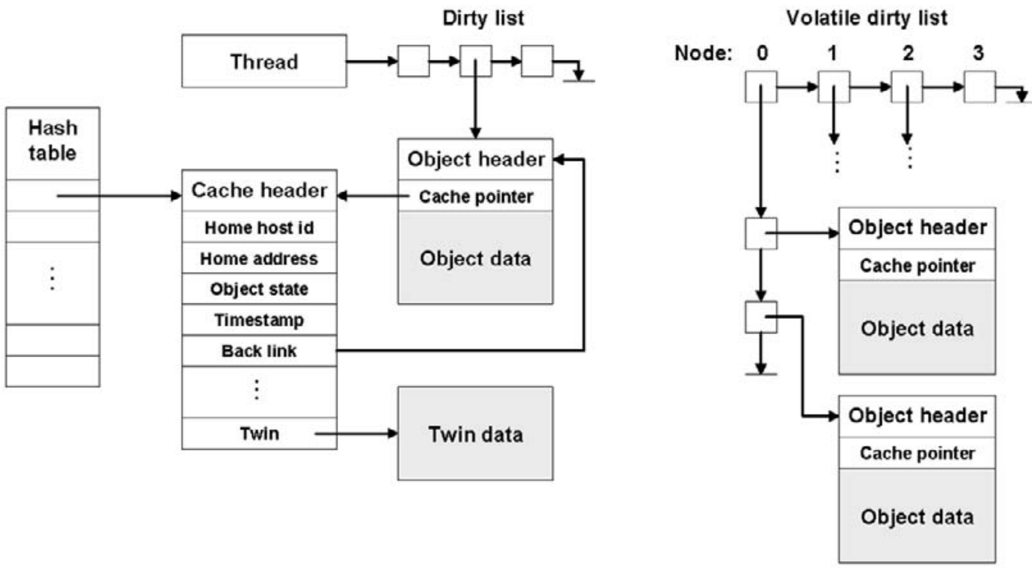
GLOBAL OBJECT SPACE

In this section, we elaborate on the design and implementation of our enhanced GOS system. We discuss the structure of the extended JVM heap, a home-based cache coherence protocol tailored for managing locks and a cluster-wide sequential consistency protocol for handling volatile field updates.

5.1 Overview of the Extended JVM Heap

To support cluster-wide object modification propagation and consistency maintenance, the heap of the standard JVM should be extended to make it "cluster-aware". In JESSICA2, each JVM heap is logically divided into two areas: the *master heap area* and the *cache heap area*. The master heap area essentially rides on the unmodified JVM heap, storing ordinary local objects. To make it "cluster-aware", when the local objects are being shared with some remote threads, they are exported as home objects with special flags marked in their object headers. The cache heap

Figure 3. GOS internal data structures



area manages cache objects brought from the master heap of a peer node. It consists of extra data structures for maintaining cluster-wide data consistency. The original GOS follows an intuitive design in which each thread has its own cache heap area, resembling the thread-private working memory based on the *Java memory model (JMM)*. This design prevents local threads from interfering each other's cache copies (such as during invalidations) but wastes precious memory space to keep redundant per-thread cache copies on the same node. So we adopt a unified cache design in the enhanced GOS which allows all local threads running on a single node to share a common cache copy. This design not only makes better usage of available memory resources but also reduce remote object fetching since when a thread faults in an object, other peer threads at the same node requesting the same object could find it in place. We also switch to a release consistency memory model in which the dominant read-only objects are never invalidated, so the interference among local threads is practically small. These modifications potentially could accommodate a high server thread count and achieve better memory utilization.

Figure 3 shows the internal data structures of the extended JVM heap. The object header of every object is augmented with special fields such as the *cache pointer*. A local or home object has a null cache pointer whereas a cache object has its cache pointer points to an internal data structure called *cache header* that contains the state and home information of the object. A node-level hash table (shared by all local threads) is used to manage and to look up cache headers during fetching events. In order to tell the home nodes of the modifications made on cache objects, each thread maintains a *dirty list* that records the ids of cache objects it has modified. At synchronization points, updates made on the dirty objects are flushed back to their home nodes. A similar per-node *volatile dirty list* is used to record updates on objects with volatile fields which are maintained by a separate single-writer protocol to be explained in section 5.3.

Object state is composed of two bits: valid/invalid and clean/dirty. The JIT compiler is tweaked to perform *inline checking* on each cache object access to see if its state is valid for read/write. Read/write on an invalid object will trigger appropriate interface functions to *fault-in* the up-to-date copy from its home. For efficiency, the software check is injected as a tiny assembly code fragment to the relevant bytecode instructions (GETFIELD, PUTFIELD, AALOAD, AASTORE, etc), testing the last two bits of the cache pointer. Valid object access passing the check will not impose any GOS interface function call overhead and is thus as fast as local object access.

Creating a single-heap illusion to distributed threads entails an advanced design of distributed cache coherence protocol as it has to be compliant to the Java memory model that defines the memory consistency semantics across multiple threads. The Java language provides two synchronization constructs for the programmers to render thread-safe code – the synchronized and volatile keywords. The synchronized keyword guarantees a code fragment or method with atomicity and memory visibility while volatile ensures that threads can see the latest values of volatile variables. We will discuss our enhancements of the GOS for handling the two types of synchronizations in Section 5.2 and 5.3 respectively.

5.2 Home-based Lazy Release Consistency Protocol

Entering and exiting a synchronized block or method correspond to acquiring and releasing the lock associated with the synchronized object. To fulfill the Java memory model, the original GOS implements an intuitive solution that works as follows. Upon a lock release, all updates to cache objects are flushed to their home nodes. Upon a lock acquire, all cache objects are invalidated, so later accesses will fault in the up-to-date copies from the home nodes. However, this would incur significant object fault-in overheads after every lock acquire. Thus, we renovate the original global object space by adopting a more relaxed *home-based lazy release consistency (HLRC)* memory model.

Contrary to the intuitive solution, upon a lock acquire, we confine invalidations to cache copies of shared objects that have been modified by other nodes only, rather than invalidating the total cache heap area. Our home-based cache coherence protocol guarantees memory visibility based on *Lazy Release Consistency (LRC)* (Keleher, Cox, & Zwaenepoel, 1992). LRC delays the propagation of modifications to a node until it performs a lock acquire. Lock acquire and release delimit the start and end of an *interval*. Specifically, LRC insures that the node can see the memory changes performed in other nodes' intervals according to the *happened-before-1* partial order (Adve & Hill, 1993), which is basically given by the local node's locking order and the shared lock transfer event. This means all memory updates preceding the release performed by a node should be made visible to the node that acquires the same lock. HLRC is similar to LRC in the sense of lock management but shapes the modification propagation into home-based patterns.

Memory updates are communicated based on a *multiple-writer* protocol implemented using the *twin-and-diff* technique that allows two or more threads to modify different parts (i.e. different fields or array portions) of the same shared object concurrently without conflict. In this technique, a *twin* copy is made as a data snapshot before the first write to a cache object in the current interval. Upon a shared lock release, for each dirty cache object, the modified part, i.e. *diff*, is differentiated from the twin. The diff is eagerly flushed to the corresponding home node, keeping the home copy always up-to-date. The thread can then safely discard the twins and diffs and close the interval. When the lock is acquired by another thread, the releaser passes *write notices* along the lock grant to the acquirer. The acquirer uses the write notices to invalidate the corresponding cached objects. It also saves the write notices so that they can be passed on to the next acquirer enforcing the happens-before partial order. A later access on an invalidated cache object will fault in the up-to-date copy from its home.

Here, we have to deal with some tricky data-race problems arising from sharing a unified cache copy among local threads. First, for systems of object-based granularity as in our case, field-level false sharing may occur since protecting different fields of one object by different locks is reckoned as well-synchronized in Java. For example, while one thread T1 holds a lock for modifying field A of a cache copy and makes it becomes in dirty state, another local thread T2 may acquire a lock for modifying field B of the same object. If another node has modified field B using the same lock, then T2 will invalidate that cache copy and fault-in the home copy, overwriting those pending modifications made by T1. Second, in systems with object prefetching, it is possible for one thread faulting in a home object A with object B prefetched to overwrite the pending modifications on the shared cache copy B made by another thread. Currently, we deal with these hazards by reconciling the timestamp field associated to each object to resolve detectable version conflicts and by incorporating techniques similar to *two-way diffing* (Stets et al., 1997).

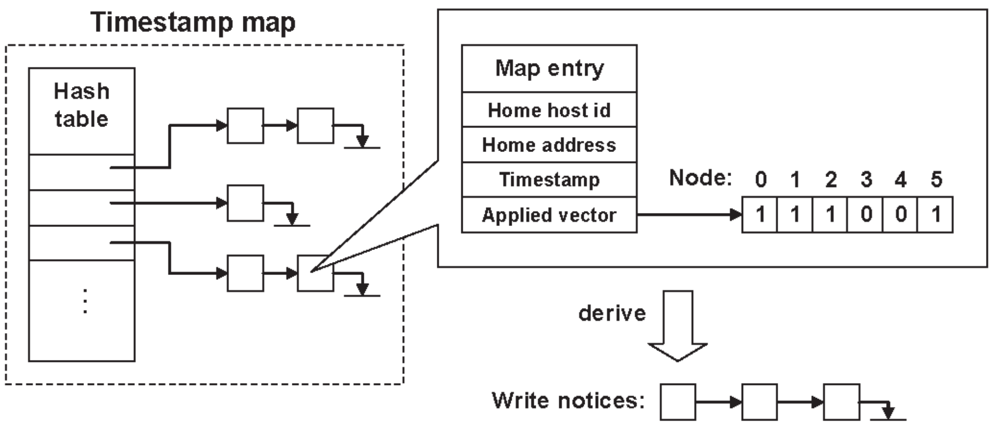
For home objects, local read/write can be done directly without generating and applying diffs. This benefit is usually known as the *home effect* (Zhou, Iftode, & Li, 1996). Some minor overhead that home nodes still need to pay is to keep record of the local writes for the next remote acquiring thread to invalidate the relevant cache copies. Locking of home objects resembles locking of local objects if the lock ownership has not been given to any remote nodes. Otherwise, it has to wait for the lock release done by the last remote acquirer.

Compared with homeless protocols, the advantages of HLRC are: 1. the home effect for reducing high diffing overheads; 2. fewer messages since an object fault can always be satisfied by one round-trip to home instead of diff request messages to multiple writers; 3. no *diff accumulation* and so no need for garbage collection of diffs. Hence, this becomes our protocol design choice for shorter latency seen by I/O-bound workload and less garbage accruing from long-running server applications.

Nevertheless, we depart from the usual HLRC implementations in some aspects. To track and enforce the happens-before partial order, traditional HLRC implementations rely heavily on *vector timestamps* to dig out the exact minimal intervals (and write notices) that the acquirer must apply. While this ensures the most relaxed invalidation, this entails complex data structures like interval records in Treadmarks (Keleher et al., 1994) or *bins* database (Iosevich & Schuster, 2005) to keep the stacks of vectors. The storage size occupied by them scales with the number of locking on shared objects. For lock-intensive applications, these stacks can grow up quickly and consume enormous space. For long-running server applications, the problem becomes more critical and systems that rely on pre-allocation schemes such as cyclic bins buffers (Iosevich & Schuster, 2005) will ultimately run out of space and result in runtime failure. Discarding interval records is possible if they have already been applied to all nodes. But some nodes may never acquire a particular lock while some nodes intensively acquire it. This issue is not ignorable particularly in multithreaded protocols where the length of vector timestamp scales with the number of threads. For highly-threaded applications like Tomcat, this has scalability impacts on both memory and network bandwidth. Therefore, our protocol eschews the use of vector timestamps.

Rather we employ object-level scalar timestamps to assist deriving the set of write notices. The basic idea is illustrated by Figure 4. Each node maintains a data structure called *timestamp map* which is essentially a hash table recording all shared objects that have once been modified. Each map entry consists of the object id, a scalar timestamp and a n-bit binary vector (n being number of nodes) and is used to derive the cor-

Figure 4. Timestamp map for implementing HLRC



responding write notice formatted as a couple (object id, timestamp). The *n*-bit binary vector is used to keep track of which node has applied the write notice (0 = not yet; 1 = applied). If all the *n* nodes have applied the write notice, it is considered *obsolete* and can be discarded. The size of this map scales with the number of modified shared objects rather than the number of shared locking. Repetitive locking on the same object will not generate separate interval records but go to update the same entry in the timestamp map. Due to high read/write ratios in web applications, the number of modified shared objects is limited. The timestamp map will also undergo a *periodic shrinking phase* to clean up those obsolete entries. So the map is practically small in size at most of the time.

Upon a shared lock release, modifications will be recorded into the local node's timestamp map. When a lock transfer happens, all non-obsolete map entries will be extracted as write notices and passed from the releaser to the acquirer. They will also be saved in the acquirer's map. Write notices with a newer timestamp will overwrite an old map entry if any and reset its *n*-bit vector to all zeros so that future acquirers will be able to know the changes. Without tracking the exact partial order, the set of write notices sent to an acquirer may not be minimal and possibly include modifications that "happens-after" the release of the lock being acquired. The drawback is that some cache objects at the acquirer side may be invalidated earlier than necessary. However this effect is insignificant since if the thread is really going to access the invalidated cache objects, it eventually needs to see the modifications. This effect will not accrue owing to our periodic cleanup of obsolete map entries and selective invalidations based on object timestamp comparison.

5.3 Volatile Consistency Protocol

Most DJVM prototype implementations enforce cluster-wide semantics of the volatile construct in a way that is stricter than necessary. For straightforward compatibility, the volatile construct is usually treated as if it was a lock, thus introducing unnecessary mutual exclusivity to the application. The latest Java concurrent utility package (JSR166, 2004), particularly the ConcurrentHashMap class shipped along, employs segment-based locks plus volatile count and object value fields to guard different hash bucket ranges. The advanced data structure offers much more scalable throughput than the conventional Java Hashtable. However, such a good design for concurrency will be smothered if the underlying DJVM handle the volatile fields as locks. So we decided to tailor consistency support to volatile fields.

Our new protocol for maintaining cluster-wide volatile field consistency is a *passive-based concurrent-read exclusive-write (CREW)* protocol. It enforces sequential consistency to ensure the next reader thread can see the updates made by the last writer on the same object.

To implement this model, we need to assign a manager for each object with volatile fields and it is naturally the home node where the object is created. For ease of explanation, we call an object with a volatile field as *volatile object*. The home node needs to maintain two states on the home copy of volatile object: *readable* and *exclusive*, as well as a list called *copyset* of the nodes that currently have a valid cache copy of this object. When the home node receives a fetch request from a node on a readable volatile object, the node's id will be added to the copyset list of the home copy. The consistency of a volatile object relies on the active writer to tell the readers of such an update. When a thread wants to write the object, no matter the home or cache copy, it must first gain the exclusive right on it from its home node. Before the exclusive right is granted to the candidate writer, the home will broadcast invalidations to all members of the copyset and clean up the copyset. The writer will record its modified objects into the per-node volatile dirty list. The exclusive right will be returned to the home along when the modification (diff) is flushed. Read/write on home objects similarly need to go through the state check except that they are done directly on the object data without diff generation and flushing. There is no need to generate any write notices because volatile cache copies are *passively* invalidated by the home when a writer exists.

Upon read on an invalid volatile object, it will need to contact the home for the latest copy and join the copyset again. If the state of the home copy is exclusive, then the fetch request will be put into a queue pointed by volatile object header. When the writer returns the diff and exclusive right to the home, the home will turn the object state back to readable and reply all queued readers with the updated object data. As long as the state of a cache volatile object stays valid, its consistency has been guaranteed and the thread can directly trust it until invalidation is received when some writer exists. This leads to the beauty of this protocol that results in much better concurrency. Reads on a valid volatile object are pure local operations without remote locks and any communications. For high application read/write ratio, our design tradeoff shifts the communication overhead of the dominant reads to writes.

PERFORMANCE ANALYSIS

In this section, we present the performance results obtained by running Tomcat on JESSICA2.

6.1 Experimental Setup

Our experimental platform consists of three tiers: 1. *web tier*: a 2-way Xeon SMP server with 4GB RAM for running the master JVM of JESSICA2 with Apache Tomcat 3.2.4 started up on it. 2. *application tier*: a cluster of eight x86-based PCs with 512 MB RAM serving as the DJVM worker nodes. 3. *data tier*: a cluster of four x86-based PCs with 2GB RAM supporting MySQL Database Server 5.0.45. All nodes run under Fedora Core 1 (kernel 2.4.22). A Gigabit Ethernet switch is used to link up the three tiers, while nodes within the same tier are connected by Fast Ethernet networks.

The initial and maximum heap sizes of each worker JVM are set to 128MB and 256MB respectively. Each database node has the same dataset replica with MySQL replication enabled to synchronize data updates across database servers at nearly real time. Jakarta JMeter 2.2 is used to synthesize varying workloads to stress the testing platform.

Table 1. Application Benchmark Suite

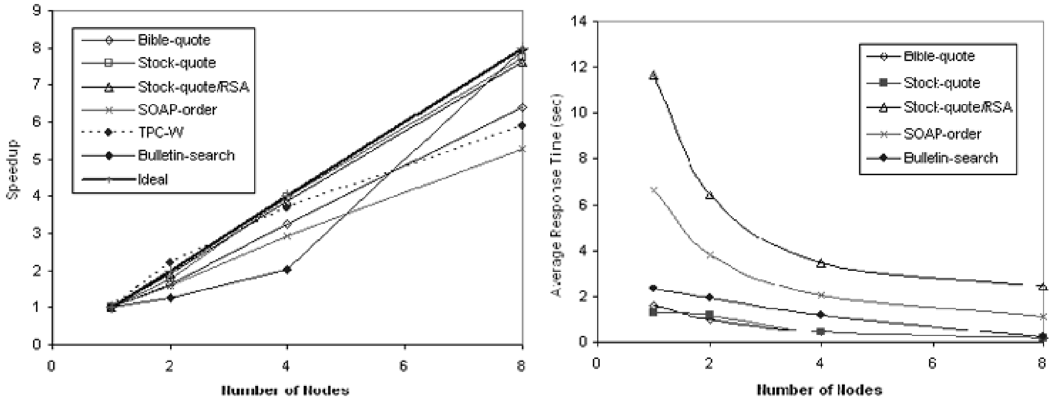
Application	Object Sharing	Workload Nature	I/O
Bible-quote	No sharing	I/O-intensive	Text files
Stock-quote		Relatively compute-intensive	Database
Stock-quote/RSA			
SOAP-order	HTTP session	I/O-intensive	
TPC-W			Database and image files
Bulletin-search	Cached database records	Memory-intensive	Database

Table 1 shows the application benchmark suite that we use to evaluate our clustering approach using the DJVM. They are designed to model real-life web application patterns.

1. *Bible-quote* characterizes applications like text search engines, news archives and company catalogs. The servlet application is I/O intensive, serving document retrievals and search requests over a set of text files of books.
2. *Stock-quote* models stock market data providers. We follow the trend of web services that deliver price data by XML messages. The application reads stock price data matching the input date range from the database and formats the query result into an XML response.
3. *Stock-quote/RSA* is secure version of Stock-quote involving compute-intensive operations of 1024-bit RSA encryption on the price data.
4. *SOAP-order* models a B2B e-commerce web service. A SOAP engine is needed to support the service. We choose Apache SOAP 2.3.1 and deploy it to Tomcat. The application logic is to parse a SOAP message enclosing securities order placements, validate the user account and order details and then put the successful transactions into the database.
5. *TPC-W* is a standard transactional web benchmark specification. It models an online bookstore with session-based workloads and a mix of static and dynamic web interactions. We adopt the Java servlet implementation developed by (ObjectWeb, 2005) but tailor the utility class for data access by disabling the default database connection pooling and utilizing thread-local storage to cache connections instead.
6. *Bulletin-search* emulates a search engine in a bulletin board or web forum system. We take the data dump from the RUBBoS benchmark (ObjectWeb, 2004) to populate the database. The application maintains a hash-based LRU-cache map of the results of the costly database searches, and is thus memory-intensive. In order not to lift up garbage collection frequency too much, we impose a capacity limit on the cache map, taking up about one-forth of the local JVM heap.

The original Tomcat is ported to JESSICA2 with a few customizations as follows: 1. the shared thread pool is disbanded. We replace the original thread pool by a simpler implementation which spawns a static count of non-pooled threads based on the server configuration file. 2. several shared object pools (e.g. static mapping tables for MIME types and status codes) are disintegrated into thread-local caches. The total lines of modified code including the new thread pool source file we introduce are less than 370 (about 0.76% of the Tomcat source base).

Figure 5. Scalability and average response time obtain by Tomcat on JESSICA2



6.2 Scalability Study

In this experiment, we measure the maximum throughputs and average response times obtained by scaling the number of worker nodes from two to eight. The speedup is calculated by dividing the baseline runtime of Tomcat on Kaffe JVM 1.0.7 by the parallel runtime of Tomcat on JESSICA2. Figure 5 shows the results obtained for each benchmark. We can see that most of the applications scale well and achieve efficiency ranging from 66% (SOAP-order) to 96.7% (Stock-quote). Bible-quote, Stock-quote and Stock-quote/RSA show almost linear speedup because they belong to the class of stateless applications, undergoing true parallelism without any GOS communications between the JVMs. In particular, Stock-quote and Stock-quote/RSA involve operations of coarser work granularity, such as string manipulations and RSA encryptions, and are hence more readily to attain nearly perfect scalability. The relatively poorer speedups seen by SOAP-order and TPC-W are expected as they are stateful applications and involve GOS overheads when sharing HTTP session objects among JVM heaps. We will further discuss the limited speedup obtained by SOAP-order in section 6.4.

Bulletin-search shows a nonlinear but steepening curve in speedup when the number of worker nodes scales out due to the implicit cooperative cache effect given by the GOS that we described in section 4. Along the scaling of nodes, when the cluster-wide aggregated available memory becomes large enough to accommodate most of the data objects cached in the application, the cache benefit will contribute an impulsive rise in speedup. Further study on this effect will be given in section 6.3.

Table 2 shows the cluster-wide thread count used in each application and the overall protocol messaging overheads inside JESSICA2 in the 8-node configuration. The count of I/O redirections is proportional to the request throughput and generally does not have impact on the scalability. The higher number of GOS protocol messages explains the poorer scalability obtained by the application if we reconcile with Figure 5. Bulletin-search is regarded as an exceptional case for its performance is more determined by its cooperative caching benefits which could supersede the cost of GOS communications.

6.3 Comparison with Existing Tomcat Clustering

A control experiment is conducted on the same platform to compare the DJVM approach with an existing clustering method for Tomcat using

Table 2. Protocol message overheads of JESSICA2 DJVM

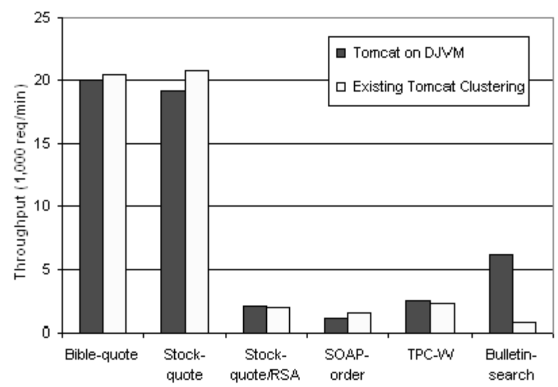
Application	# Threads	# GOS Messages / Sec	# I/O Redirections / Sec
Bible-quote	80	0	2006
Stock-quote	80	0	1791
Stock-quote/RSA	80	0	275
SOAP-order	16	979	146
TPC-W	40	351	1413
Bulletin-search	16	483	297

web load balancing plug-ins. We run an instance of Apache web server 2.0.53 on the web tier and eight standalone Tomcat servers on the application tier of our platform. The web server is connected to the Tomcat servers via the mod_jk connector 1.2.18 with sticky-session enabled (in-memory session replication is not supported in this comparison). The cluster-wide total number of threads and heap size configurations in this experiment are equal to the previous ones used in the DJVM approach.

Figure 6 shows the throughputs obtained by the two clustering approaches on eight nodes. We can see that both solutions achieve similar performance (within ±8%) for those stateless web applications (Bible-quote, Stock-quote and Stock-quote/RSA). These applications exhibit embarrassing parallelism and will not gain much advantage from the GOS. So putting the GOS aside, we can expect both solutions should perform more or less the same because both our transparent I/O redirection and mod_jk's socket forwarding are functionally alike for dispatching requests and collecting responses. Yet, extra overheads could be incurred in our solution when transferring big trunks of data via fine-grain I/O redirections and during object state checks.

TPC-W performs about 11% better on the DJVM than with mod_jk. One reason is that servers sharing sessions over the GOS are no longer restricted to handle requests bounded to their sticky sessions while load hotspots could happen intermittently when using mod_jk. On the other hand, SOAP-order performs 26% poorer on JESSICA2 than with mod_jk. The main factor that pulls down the performance is that the SOAP library has some code performing fairly intensive synchronizations in every request processing cycle. We will see later that the overhead breakdown presented in Section 6.5 echoes this factor. Bulletin-search performs 8.5 times better on the DJVM due to application cache hits augmented by the GOS. We will explain why the DJVM approach has significantly outplayed the existing solution in the next section.

Figure 6. Comparison of Tomcat on DJVM and existing Tomcat clustering



6.4 Effect of Implicit Cooperative Caching

Bulletin-search exemplifies the class of web applications that can exploit the GOS to virtualize

Table 3. Bulletin-search's cache size setting and hit rates augmented by GOS

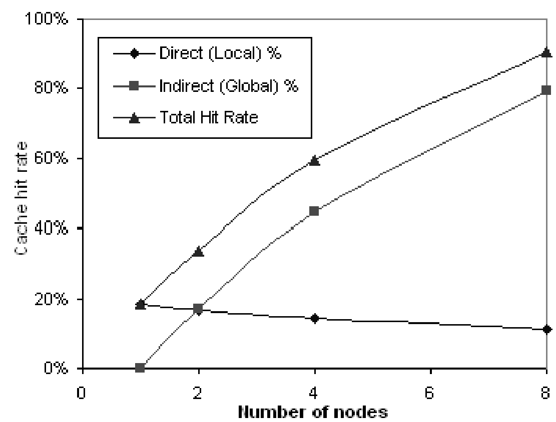
No. of Nodes	Cache Size (#Cache Entries)	Relative Cache Size	Total Hit Rate	Indirect Hit Latency (ms)	Cost Ratio of Miss: Indirect Hit	Throughput Speedup
1	512	12.5%	18.6%	N/A	N/A	N/A
2	931	22.7%	33.9%	9.07	40.79	1.26
4	1862	45.5%	59.3%	8.18	45.23	2.02
8	3724	90.9%	90.7%	11.74	31.52	7.96

a large heap for caching application data. Table 3 shows the application cache hits obtained by Bulletin-search when the number of cluster nodes scales from one to eight. With the GOS, the capacity setting of the cache map can be increased proportional to the node count beyond the single-node limit for different portions of the map are stored under different heaps. This is not possible without the GOS. Upon the creation of a new cache entry, its object reference built to the map is brought visible to all threads across synchronization points. So redundant caching is eliminated. Threads can exploit *indirect (or global) cache hits* in case the desired object is not in the local heap, easing the database bottleneck.

We can see from Figure 7 that the overall hit rate keeps rising along with the scaling of worker nodes of the DJVM and most of the cache hits are contributed by the indirect hits when the single-node capacity has been exceeded. This is the reason why our approach achieves a multifold throughput than the existing clustering approach in which there are only direct (local) hits that would level off or even drop slightly no matter how many nodes are added.

Here we define a term called *relative cache size (RCS)* that refers to the percentage of the aggregated cache size (combining all nodes) relative to the total size of the data set. When the RCS is below 50% in the 4-node case, the achievable cache hit rate is only around 60% and the 40% misses get no improvement such that the application obtains a speedup of merely two. But when the RCS exceeds certain level (e.g. 90% in the 8-node case), most of the requests are fulfilled by the global cache instead of going through the database tier. This explains the non-uniform scalability curve of this application in Figure 5.

Figure 7. Composition of application cache hits in Bulletin-search with GOS



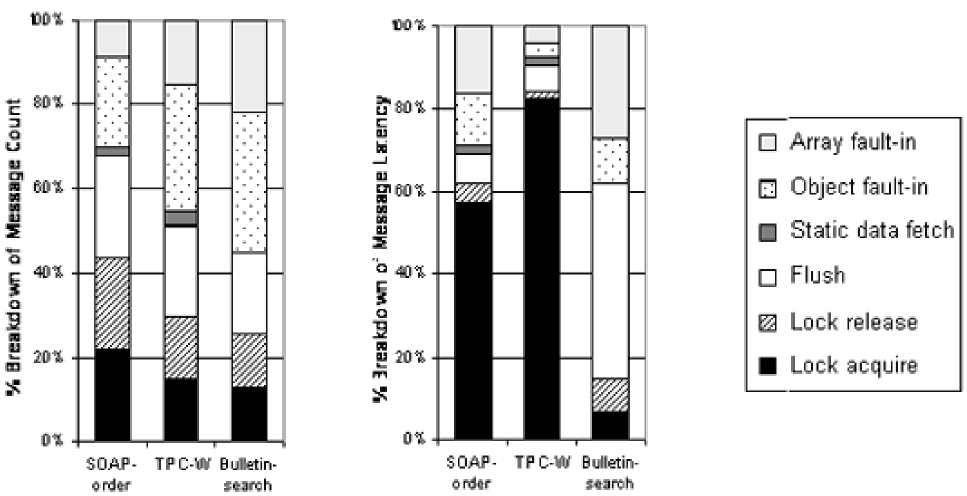
6.5 GOS Overhead Breakdowns

Table 4 shows the GOS overhead breakdowns in terms of message count per second for the three stateful applications. Figure 8 supplements with percentage breakdown of the message count as well as message latency. Lock acquire and release messages are issued when locking a remote object. Flush messages are sent upon lock releases but the flush message count is a bit more than lock release messages because in some cases updates are flushed to more than one homes. Other overheads are related to access faults which translate

Table 4. GOS overhead breakdown

GOS Message Type	# Messages / Sec		
	SOAP-order	TPC-W	Bulletin-search
Lock acquire	198	48	61
Lock release	198	48	61
Flush	217	70	92
Static data fetch	18	10	0
Object fault-in	197	99	160
Array fault-in	79	50	105

Figure 8. GOS percentage overhead



to communications with the corresponding home nodes. It is obvious that SOAP-order involves much more remote locking overhead than the other applications.

Our further investigation finds that one utility class of the deployed SOAP library would induce for each request about five to six remote locks on several shared hash tables and four remote locks on ServletContextFacade coming from the facade design pattern of Tomcat. Such heavy cluster-wide synchronization overheads justify the relatively poorer scalability given by this application.

Table 5 presents the local and remote locking rates for each application. We can see that local locks are much more than remote locks. The main reason behind this is that in Java-based servers, thread-safe reads/writes on I/O stream objects are exceptionally frequent, producing tremendous local locks. While local lock latency is very short (benchmarks shows an average of 0.2us), remote lock latency is however at least several thousand times longer in commodity clusters; yet remote locks are practically much fewer in most web applications. Another piece of information given by Table 5 is that SOAP-order and TPC-W have about 35% to 45% remote locks under cluster-wide contention, thus prolonging the wait time before locks are granted. This is why lock acquire has been the dominant part in the message latency for these two applications in Figure 8.

Table 5. Cluster-wide locking overheads

Application	# Local Locks / Sec	# Remote Locks / Sec	% Remote Locks Under Contention	Ratio of Local: Remote Locks
SOAP-order	232631	198	35%	1175:1
TPC-W	240470	48	45%	5010:1
Bulletin-search	27380	61	6.5%	449:1

RELATED WORK

Despite the boom of software DSM and the later DJVM research, it seems there have been only a few attempts at transparently supporting real-life server applications by means of shared virtual memory systems. Even fewer have been successful cases demonstrating good scalability though some of them had relied on non-commodity hardware to support their systems.

Shasta (Scales & Gharachorloo, 1997) is a fine-grained software DSM system that uses binary code instrumentation techniques extensively to transparently extend memory accesses to have cluster-wide semantics. Oracle 7.3 database server was ported to Shasta running on SMP clusters, albeit without success in achieving good scalability. They used TPC-B and TPC-D database benchmarks which model online transaction processing and decision support queries respectively. TPC-B failed to scale at all due to too frequent updates while TPC-D strived to achieve a speedup of one point something on three servers connected by non-commodity Memory Channel Network. To some extent, their experience and result exhibit many limitations of implementing a single system image at operating system level, compared to our approach of clustering at middleware level. For example, relaxed memory consistency model cannot be adopted at operating system level in usual cases, since correctness of binary applications often relies on consistency model imposed by hardware, which is generally much stricter than Java memory model. Being able to adopt relaxed memory model such as HLRC in our case is very important to server applications which may be intensive in synchronization.

cJVM (Aridor et al., 1999) is one of the earliest DJVM designed with intent to enable large multithreaded server applications such as Jigsaw to run transparently on a cluster. cJVM operates in interpreter-mode; it employs a *master-proxy model* and a *method shipping* approach to support object sharing among distributed threads. The system relies on proxy objects to redirect field access and method invocation to the node where the object's master copy resides. This model basically conforms to sequential consistency and is not efficient since every object access and method invocation may require communication although some optimization techniques were developed to avoid needless shipping. In contrast, our DJVM runs in JIT-compilation mode and conforms to release consistency, both propelling faster execution. In (Aridor et al., 2000), cJVM was evaluated by running pBOB (Portable Business Object Benchmark), a multithreaded business benchmark inspired by TPC-C, on a 4-node cluster connected by non-commodity Myrinet. They obtained an efficiency of around 80%. However, it is unclear that whether cJVM will perform such well if JIT gets enabled and commodity Ethernet is used as in our case.

Terracotta (Zilka, 2006) is a JVM-level clustering product emerged on the market for a couple of years. It applies *bytecode instrumentation* techniques similar to JavaSplit (Factor, Schuster, & Shagin, 2003) to a predefined list of common products and to user-defined classes for clustering among multiple Java application instances. Users need to manually specify shared classes as *distributed shared objects (DSOs)* and their cluster-aware concurrency semantics. Contrasting with our SSI-oriented approach, this configuration-driven approach may impair user transparency and create subtle semantic violation. Terracotta uses a hub and spoke architecture that requires setting up a central server, namely the "*L2 server*", to store all DSOs and to coordinate heap changes (field-level diffs) across JVMs. At synchronization points, changes on a DSO have to be sent to the L2 server that forwards the changes to all other clustered JVMs under the DSO's copyset to keep all replicas consistent. Our home-based protocol needs to keep only the home copy up-to-date by flushing diffs, then the next acquirer can see the changes by faulting in the whole object. Terracotta's centralized architecture may make the cluster susceptible to a global bottleneck when scaling out. Tailoring the bottleneck requires forklift upgrades on the L2 server (i.e. vertical scaling) that spoil the virtue of horizontal scaling using commodity hardware. We believe a home-based peer-to-peer protocol is a more scalable architecture for distributed object sharing.

CONCLUSION AND FUTURE WORK

In this chapter, we introduce a new transparent clustering approach using distributed JVMs (DJVMs) for web application servers like Apache Tomcat. A DJVM couples a group of extended JVMs for distributing a multithreaded Java application on a cluster. It realizes transparent clustering without the need for introducing new APIs and incorporates most of the advantages of a SSI-centric system such as global resource integration and coordination. Using DJVMs to cluster web application servers can enhance the ease of web application clustering and global resource utilization – both have been poorly met in most existing clustering solutions among the web community.

We port Tomcat to the JESSICA2 DJVM to testify this clustering approach. Our study addresses new challenges of supporting web application servers that characterize unique runtime properties of today's object-oriented servers over the classical scientific applications evaluated in the previous DJVM projects. The key challenge lies in making the system scalable with a large number of threads and offering efficient shared memory support for fine-grain object sharing among the JVMs. We enhance the cache coherence protocol design accordingly in several aspects: 1. adopt a unified cache among local threads to make better memory utilization; 2. implement a timestamp-assisted HLRC protocol to ensure release consistency of shared objects; 3. enforce sequential consistency among cluster-wide volatile fields via a concurrent-read exclusive-write (CREW) protocol. These improvements result in more relaxed coherence maintenance and higher concurrency. Our experimental result has illustrated significant cache hits obtained by using the global object space (GOS) to cache a large application dataset with automatic consistency guarantee.

Several trends have put forward the advent of the DJVM clustering technology. Today's web applications are becoming increasingly resource-intensive due to security enhancement, more complicated business logics and XML-based standards. Collaborative computing paradigm provisioned by DJVMs becomes vital to generate helpful cache effect across cluster nodes for efficient resource usage. Second, application logics tend to increase in complexity and now more and more application frameworks are POJO-based. Clustering at application level and adoption of proprietary clustering mechanisms shipped with particular application server products will tend to be laborious and error-prone, if not unfeasible. We foresee DJVMs, typifying the kind of generic clustering middleware systems, will be gaining more user acceptance. Third, design and development for user applications, server programs and library support nowadays have put more emphasis on scalability than ever. When scalability or performance portability is not a problem and meanwhile DJVMs are supreme in cost-effectiveness, this would have a catalytic effect that more applications readily go for the DJVM technology.

In future, we will investigate solutions to enhance fine-grain object sharing efficiency in the DJVM environment. In our research plans, we would consider incorporating transactional consistency (Hammond et al., 2004) into the cluster-wide memory coherence protocol.

KEY TERMS AND DEFINITIONS

Copyset: The current set of nodes or threads that hold a valid cache copy of an object. This data structure is kept at the home node of the object and is helpful for sending invalidations in a single-writer-multiple-reader cache coherence protocol.

Distributed Java Virtual Machine (DJVM): A parallel execution environment composed of a collaborative set of extended Java virtual machines spanning multiple cluster nodes for running a multithreaded Java application.

Global Object Space (GOS): A virtualized memory address space for location-transparent object access and sharing across distributed threads. The GOS for distributed Java virtual machines is built upon a distributed shared heap architecture.

Java Memory Model (JMM): A memory (consistency) model that defines legal behaviors in a multi-threaded Java code with respect to the shared memory. The JMM serves as a contract between programmers and the JVM.

Lazy Release Consistency (LRC): The most widely adopted memory consistency model in software distributed shared memory (DSM) in which the propagation of shared page/object modifications (in forms of invalidation/update) is delayed to lock-acquire time.

Implicit Cooperative Caching (ICC): A helpful cache effect created by distributed threads through cluster-wide accesses to a collection of shared object references.

Chapter 8.10
Virtual Web Services:
Extension Architecture to Alleviate Open Problems in Web Services Technology

ABSTRACT

Several open issues in Web services architecture are being solved by using different kinds of solutions. Standard high-availability techniques based on the use of Web servers, business-logic-based caching systems, dynamic binding of Web services by programming the access to a SOAP message content from the business logic layer, and other kinds of current open problems can now be handled using a common unique technique. What we propose is to apply virtualization techniques to Web services.

INTRODUCTION

When referring to current Web service architecture, a very important aspect to take care of is the one related to the separation of roles and the meaning of each role inside the architecture. Although the distinction between client, provider, and directory is clear, a great part of the Web services technology is based on a Web service offered by a provider (Booth, Haas, McCabe, Newcomer, Champion, Ferris et al., 2004). That is, according to the roles of the current proposed architecture, the provider is intimately related to the Web service it actually offers. In fact, both Web service and provider are used as only one role inside the architecture, called service provider. Several open problems of the current architecture can be solved by redefining this way of conceiving the roles inside the architecture.

Within the current architecture, the relation between client and provider has been established based on the use of two concepts:

- *Binding*. It is a process performed at development-time, consisting of adapting client software to the definition or description of a Web service.
- *Invocation*. It takes place on runtime, and it can be defined as the process by which a running client application calls a Web service.

The revised version of the W3C architecture redefines and merges these two concepts as "interaction." According to an "interaction" between client and provider, the binding is performed in a static way, so the way invocations must be performed is predefined. According to this:

- Dynamic binding cannot be performed, or, at least, not in an automatic way. There are different options based on the use of metadata ("Web services invocation framework," 2007) that enable the use of dynamic binding, but it is always mandatory to use metadata to access application data.
- Once a client application is bound to a concrete Web service, the execution of the application will be bound to the service provider selected, initially, at development-time. It will be necessary to bind a new Web service if we decide to use a new service provider. And this means that it will be necessary to develop new code to adapt the client application to the new interface of the new Web service. Although it is possible to change the location of the server providing the Web service without needing to make any modification to client application code, this will be only useful for those providers that have developed and published a Web service in the same way, that is, with the same parameters (its names and types), the same namespaces, and so forth.
- If a client application wants to use more than one provider in order to invoke the same equivalent service (offered by different service providers), the developer must bind the client application to each one of the Web services.

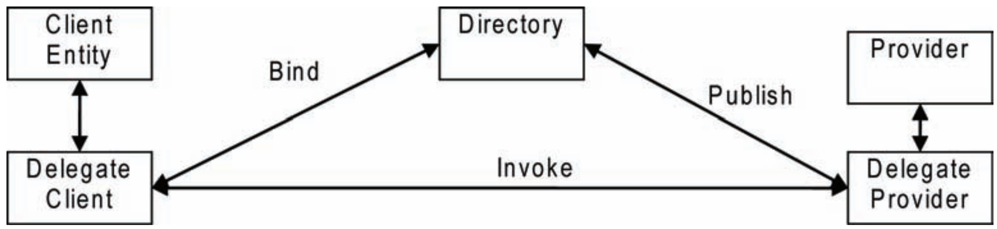
These and other less relevant problems have their origin in the fact that the role of "service provider" is not distinguished from the role of "Web service provider." When we talk about service-oriented architectures (SOA) (Barry, 2003; Vinosky, 2002), we usually use the terms "clients" and "providers," and we always relate these term with the use of services. We think it is necessary to slightly change the terminology, and use the terms "client application" when we refer to a SOA client, and "Web service provider" when we refer to a SOA provider.

In addition, we propose the creation of two new roles (as seen in Figure 1): the service provider (differentiated from the Web service provider), and the client entity (differentiated from the client application). The appearance of these two new roles will led us to a mandatory role separation. That is, Web services architecture is now composed of five roles: client entity, client application, directory, Web service provider, and service provider.

STATE OF THE ART

In the following subsections we will analyze the state of the art in several open issues in the Web services technology.

Figure 1. New roles



High Availability (HA)

When using production systems, the availability of a system is one of the most important issues to care about. HA is not considered as a part of the Web services architecture, but infrastructure providing companies (e.g., application servers, Web servers, load balancers, etc.) propose to increase the availability of a Web service by means of enhancing the availability of its underlying infrastructure.

There are two alternative ways to enhance the availability of a system:

- **Fault-tolerant systems**. All the hardware components in a fault-tolerant system are redundant (memory, processor, etc.), so, in case of a component fault, the whole system will continue running.
- **Cluster systems**. A cluster system is made of several computers (servers) that communicate using a high speed local area network (LAN). If a server fails, the whole cluster will continue running.

It is also possible to find mixed hardware configurations where fault-tolerant systems are used to build a fault-tolerant cluster, like Sysplex® (Nick, Chung, & Bowen, 1996), and cluster systems are made up of nodes build with redundant components.

As a result of hardware availability enhancement, providers protect their systems in order to offer the highest possible availability. But client's point of view is really different. If a provider stops accepting and responding invocations due to a problem in any hardware or software component (or even in the network), what clients notice is a system outage, that is, 0% availability, since the clients do not have any other way of invoking the service.

This situation can really happen, and it is due to the fact that the providers protect the implementation, while clients invoke an interface. Actually, all issues related with production systems of Web services (i.e., availability, scalability, etc.) have had no special attention inside current Web services architecture. The solution to all of them is always focused oi the implementation, not the interface.

Due to these lacks, client applications cannot have an assured minimum availability, since they are bound to a concrete provider, who may not comply with the conditions of a contract with that client. If clients could select automatically a provider when detecting an error condition, the availability of the service (independently of the provider used) would increase. This increment would be obtained independently of the availability of the implementation.

When enhancing the availability of a Web service, as we have mentioned above, protecting the implementation is not enough. The interface, what clients really use, should be equally protected. How? Just untying interface and implementation so the point where request from clients are received and the point where they are solved are really different and independent.

In order to reach this independence we propose the use of **indirect invocation**, so the interface can be published at an intermediate layer (responsible of dialoguing with clients), and the implementation is performed at a different layer, far from clients and invoked from the intermediate layer. This way, the intermediate layer can have some decision capabilities in order to, by publishing one only interface, invoke different implementations that reside in different points or nodes.

Quality of Service (QoS)

The term quality of service (QoS) refers to a set of techniques and technologies used with the aim of offering predictable results. For example, QoS techniques are used to assure a minimum bandwidth, a limited error rate, or a percentage of network availability. QoS is actually a concept that can be applied to any entity that provides a service, and from this point of view, a Web service can be analyzed from a QoS optic.

Variables like performance, response time, or availability can be used to measure the QoS of a Web service. But clients are also interested in other type of variables, that is, variables related to the provider of the service, and not just the Web service. That is, clients may be interested in things like provider cost or reliability. Once again, it is very important to separate the roles of service provider and Web service provider. Actually, we are talking about the need of differentiating "service metrics" (provider related) from "Web service metrics" (Web service related).

From clients' point of view, it is very important to know the value of a Web service's availability, for instance. But it is even more important to know the value of the availability of a service depending on the cost of that service. This assertion can be applied to any number of variables.

Independently of the number of variables that a client wants to handle, it is necessary for the client to handle them separately, differentiating the ones that define the behaviour of a Web service from those that define the behaviour of a Web service provider. The interface of a Web service has several associated metrics, but the implementation of that service has another different set of metrics.

There are several works published related to the QoS issue (e.g., Conti, Kumar, Das, & Shirazi, 2002; Menasce, 2002), but all of them only care about defining metrics, and they do not offer an architecture for implementing QoS. In addition, they do not offer the possibility to differentiate Web service metrics from provider metrics.

Weller (2002) analyzes a theoretical mechanism for qualifying Web services. According to this study, a new component is added to the standard architecture components, that is, the qualification repository, where clients store qualifications about providers, and other clients request qualifications about providers in order to perform an invocation. The repository computes and stores all qualifications about providers.

Our purpose of indirect invocation based on the use of expressions allows the use of any kind of variables in order to qualify a Web service and/or a service provider, and to obtain a unique value that can be used to select the most appropriate Web service at a given moment, according to a concrete QoS.

Multiprovider

As Web services technology grow, more provider companies will use it. That is, client entities will have an opportunity to enhance client applications, since they can use an increasing number of providers that will offer the same or equivalent service. But, for instance, they will differentiate in their availability, cost, or performance.

This ability to use more providers will become an additional new work when developing client applications, since each provider will use its own namespaces, schemas, parameters, and so forth. So, it will be mandatory to write ad-hoc code to integrate each one of the used providers into client applications, and developers will need to carry out more expensive and cost-consuming development processes.

Our purpose based on the virtualization of Web services, permits, in a natural way, to use multiple providers for only one Web service. As we will see below, Web services are published in a virtual way, while implementation of Web services can be performed by multiple different providers.

Error Management

The common lifecycle of a client application using Web services includes, at least, the following processes:

- To look for a Web service and a provider.
- To locate the description of the Web service (Web service definition language [WSDL] document).
- To perform a binding process, in order to build proxies, which will be the ones used to perform the invocations. This process will normally produce a set of modules that hold the definitions of: (i) the class of input data, (ii), the class of output data, and (iii) the invocable methods with its input and output parameters according to previous defined classes.

When a client application invokes a Web service, it is responsible of checking and handling any error condition that can occur. The following checklist should be implemented inside client applications:

- Invoke service.
- Check error.
- If invocation is not successful, determine if invocation can be retried.
- Retry the invocation a finite number of times.
- If invocation cannot be performed, send an error.

Let us consider having a client application bound to a Web service, and we want to stop using our current provider in order to use a new one (due to its low availability, for instance). We will have to modify our client application in order to delete all the references to the old provider and add new references (i.e., URL, types, namespaces, etc.) to the new provider.

In addition, it is usual (and it will become more usual in the future) to have more than one provider for the same service, in such a way that if one provider fails, client applications can invoke another provider.

With the aim of increasing the availability of client application, developers can decide to add more providers (and bind them) to that client application. This way, client application can retry invocation with a provider in case of an error of another one. But, according with what we have said above, a new checklist should be used:

- Invoke service.
- Check error.
- If invocation is not successful, determine if invocation can be retried.
- Retry the invocation a finite number of times.
- Select a new provider from the list of candidates and try again.
- If invocation cannot be performed, send an error.

As we can see, development and maintenance processes get more complex as we add more flexibility and availability to client applications. By using our purpose, we will be able to build Web services whose implementation is based on the selection and usage of several different and equivalent providers. This way, we will have a chance to enhance the availability of client applications without the need of complex development processes.

Caching

It is easy to understand how to implement a caching system when we talk about Web pages (HTML pages, images, etc., that is, static information). However, where (and how) can we apply caching techniques to Web services entirely based on the use of dynamic information (i.e., SOAP messages in response to different SOAP requests)? Our purpose enables the use of caching inside Web services technology, but it is important to take into account the fact that caching techniques can be applied to Web services only under specific circumstances:

- The number of invocation requests is large enough. If so, there will be a significant increase in performance when using a caching system.
- There is at least a method (a WSDL port, let us call it a "cacheable method") whose response to a request can be repeated along time without any variation in SOAP responses. If not, it may not be adequate for implementing caching mechanisms.
- The results received by clients invoking a cacheable method when the response is cached must not differ from those received by clients when the response is not cached.

Different applications in real life can be eligible to be implemented using cacheable Web services. Some examples of cacheable Web services are:

- A Web service that provides weather forecast, where changes in responses are not expected to occur in a short time.
- A Web service to obtain stock market share prices. Although this is a typical real time application (clients obtain real prices on each invocation), consider how the service runs when there are no changes to price, or when the stock market is close.
- A Web service to obtain the status of an item in relation to a stock management service (e.g., available quantity, type, model, etc.).

ARCHITECTURE DEFINITION

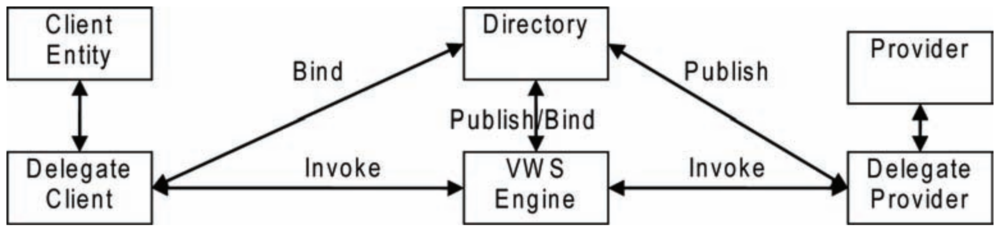
Our proposed architecture for the use of virtual Web services (VWS) determines the existence of, at least, five components (Figure 2): a client (client entity), a delegate client (client application), a service provider, a delegate provider (Web service provider), and a VWS engine. The client is the one who needs a service and, by the use of a delegate client, performs an invocation. The service provider is the one that publishes and offers a service through a delegate service provider. In our VWS architecture, invocations are not performed directly from the delegate client (typically a client application) to the delegate service provider (typically a Web service), but rather the delegate client performs an invocation to a VWS engine, who acts as an intermediary, and the engine performs an invocation to the delegate provider.

The VWS engine is not a virtual server. It is a standard server, and it should be implemented in the same way as a server used to process standard Web service invocations. The term "VWS engine" refers to a server that is capable of understanding virtual Web service definitions. That is, it can receive, process, and respond to standard Web service invocations, and, in order to process a request, the engine uses VWS definitions to select and invoke the most suitable Web service.

IMPLEMENTATION AND DEFINITION LANGUAGES

Any application that is able to use a standard Web service can be bound to a virtual Web service. Our virtualization technology provides a definition language (an XML-based language). This

Figure 2. Virtualization-based architecture



language (VWS definition language [VWSDL]) is used to write VWS documents. Clients do not use VWS documents, since these documents are just a definition of an implementation of a virtual Web service, and this definition is only useful to VWS engines. Our proposed language has been defined as a stand-alone language, that is, not as a WSDL extension, since its intended use is completely different. Even though the main objective of both languages is the same (describe a Web service), the way in which services are described are completely different.

VWS documents are used to describe virtual Web services, and they must contain, at least, a list of methods provided by the service (using the method elements, as shown in Figure 3). In addition, for each method published inside a service, we must specify the input and output parameters, and their corresponding data types.

As shown in Figure 3, each method element has its own name and type attributes. The type attribute is used to specify the type of implementation that is being defined. For instance, the equivalent value states that, in order to execute a virtual method, a set of "equivalent" services are available to accomplish the execution. The content of a method element is also used to specify a list of Web services and methods that will be invoked in order to complete the execution of a method. All those Web services and their methods represent in fact the implementation of a virtual method, and they are specified (inside the method element) using so many invoke elements as needed.

In SOAP language, parameters are nominal, that is, input parameters sent to methods use the name of the elements (XML elements). The same happens with return parameters. Let us suppose that we build a virtual method that receives a parameter called "P1" and returns a parameter called "RP." This represents a little restriction in the way we write the method and invoke elements, since the name of the parameters used in the virtual method must match the ones used in real methods. If a match can be found, the invoke elements can be used without a problem. When such a match cannot be found, a map element should be used to solve this situation. The map element can contain a set of in and out elements that are used to specify the correspondence between virtual parameters and real parameters. Inside each subelement (in or out), we must write an origin parameter name and a destination one, so the engine knows how to map the parameters before and after each invocation.

It is possible to find equivalent services that use similar parameters with different data types; a price is a typical example that can be handled using integer types or float types. In situations like this, a conversion process must be performed. This conversion is expressed via the type attribute. It is also possible to map a simple type to an element contained inside a complex one using XPath expressions, that is, assigning a simple value extracted from a DOM node.

The use of the map element brings much new functionality to the virtualization technique, since parameter mapping between virtual and

Figure 3. Sample method declaration

```

      <select name="COS#1" expression="0.7*adjust(availability)+0.3*reverseAdjust(cost)" />
      <select name="COS#2" expression="0.5*adjust(availability)+0.5*adjust(security)" />
    <input>
      <parm name="ticker" type="xsd:string"/>
    </input>
    <output>
      <parm name="name" type="xsd:string"/>
      <parm name="value" type="xsd:float"/>
      <parm name="date" type="xsd:date"/>
    </output>
    <invoke id="2" method="sendItToMe" location="http://a.com/s1.wsdl">
      <map>
             <in origin="/ticker" target="t"/>
             <out origin="/name/shortName" target="/name"/>
             <out origin="/price" target="/value" type="relaxed"/>
      </map>
    </invoke>
      <...>
</method>
```

real services lessens the coupling level between client applications and service implementations. Some benefits we obtain include deploying new versions of implementation Web services with the same interface, and new interface versions using the same implementation Web services.

Expressions

In order to explain the expression system, let us consider the existence of three variables that can be used to define a Web service and/or a provider: availability, cost, and security.

When a client application needs to invoke a service, the client must decide which would be the most appropriate provider. Normally, a client would choose the one that has the lowest cost, the highest availability, and the highest security level. In our example, the client should choose service B according to the cost, service A according to the availability, service C according to the security level. To solve situations like this, what our VWS architecture proposes is to build an expression that combines all the variables and gives a unique value, pondering each one of the variables using factors. This way, a sample expression combining all three variables could be written as Expression (1).

```
0.6*A + 0.3*C + 0.1*S (1)
```

where A represents the availability, C is the cost, and S is the security level. To be able to write expressions in which we can mix different types of variables, having each one its own unit (milliseconds, dollars, etc.), we must apply a conversion factor in order to represent all the variables within the same scale. In addition, we should keep in mind the fact that some variables maximize the value of the whole expression by means of their maximum values (availability, for instance), while other variables do the same with their minimum values (cost, for instance).

In order to unify scales, ranges, and units for all variables used in an expression, the function adjust can be used. In addition, for variables whose minimum values represent a maximum scoring, the function reverseAdjust is available. Expression (1) can be rewritten as Expression (2) using these new functions.

```
0.6 * adjust(A) + 0.3 *
reverseAdjust(C) + 0.1 *
adjust(S) (2)
```

When an invocation request is received at the VWS engine, the engine must calculate the scaling factors to unify the scale of the variables that will be used in the expression. An example is shown in Figure 3 (select elements).

Complex Expressions

Two additional methods will allow writing complex expressions: complex variables and time-variables. A complex variable is a new variable that is created using a combination of simple ones. In Expression (3), a variable defined as G is used to hold a value that represents a global score for a provider, using A, C, and S.

```
G = 0.6 * adjust(A) +
0.3*reverseAdjust(C) + 0.1 *
adjust(S) (3)
```

$$adjust\ ((W*G_{i-1} + G_i) / (W + 1)) \quad (4)$$

On the other hand, time-variables allow writing expressions that involve present and past values of a variable. For example, Expression (4) can be used to obtain a global qualification for a provider, where time is taken into account by using two global-score values (i.e., G_{i-1} for the previous computed value of G and G_i for the present value of G), and a weighting factor (W) that is used as a stabilization mechanism.

External Variables

Our virtualization architecture does not impose any kind of constraint when writing expressions or using variables, and so we can use external variables managed by an external entity. For example, we could write an Expression (5) that includes an external status variable (T) indicating the status of the Web service. If a Web service is "out-of-service," we can set T to zero, and the VWS engine will stop selecting it.

T*(0.4*reverseAdjust(C) + 0.6*adjust(A)) (5)

Extension Mechanisms

Our virtualization architecture proposes the use of two additional mechanisms in order to help clients in having some decision capabilities over the evaluation process. The main objective of these mechanisms is to give the clients the ability to drive the evaluation process performed at the VWS engine.

The first mechanism is based on the use of classes of service (CoS). A CoS is defined (according to our purpose) by writing a concrete expression inside a method element (using a select element). More than one CoS can be defined by writing so many select elements as needed, identifying each of them with a name. Each select element represents in fact a given class of service. Once several classes of service have been defined inside a VWS document, clients can specify what CoS to use in each invocation by using SOAP extensions.

If a client does not specify what CoS to use, the VWS engine should use a default CoS in order to perform an invocation.

The second extension mechanism allows the client applications to prune the list of eligible Web services. Clients can send, attached to the SOAP requests, a set of conditions that implementation Web services must fulfill (Figure 4). This way, when the VWS engine has to perform an evaluation, it will consider only those services that fulfill the client's conditions.

The base for the implementation of our extension mechanisms is the use of SOAP header elements. Like other standards, we propose to add specific extension information to the header of SOAP response messages. The information contained in a SOAP header must obey a schema

Figure 4. Sample restriction

```
<retriction select="(availability &gt; 95) and (cost &lt; 20)" cos="COS#2" />
```

in order to use our cache purpose, that is, a virtual Web services extension language (VWSEL) (Fernández, Pazos, & Fernández, 2005), created as an extension of our VWSDL (Fernández, Pazos, & Fernández, 2004). VWSEL is used in our virtualization-based architecture to offer clients a chance to send processing information to VWS engines, such as classes of service, lists of providers, preferences about caching, and so forth.

Client applications must understand VWSEL in order to use VWS extensions. It is important to note that clients who do not understand VWSEL can still work without a problem, since a SOAP message (aside from including VWSEL data) is still a standard SOAP message that can be processed by client applications, engines, and providers.

It is responsibility of every Web service to decide what information will be included inside the VWSEL section of SOAP messages. Web services should use VWSEL documents to send only caching information to clients.

QUALIFICATION AND EVALUATION

Variables are used inside our solution to achieve the automation of two processes:

- A **qualification process:** The VWS engine computes and stores statistical information in a database after selecting and invoking a Web service. The same or another engine will use that statistical data in a later moment.
- An **evaluation process:** By means of this process, a VWS engine reads statistical information stored in the database, with the aim of selecting and invoking the most suitable Web service to accomplish the execution of a virtual service method.

We have already seen how to build expressions in which we can put together all we know about the way a given Web service works. The objective of expressions is to achieve quick and automated qualification and evaluation processes. Theoretically, every time a Web service is invoked, the VWS engine should update the statistical data related to that service.

Nevertheless, by means of a good performance, it could be good practice not to store all the gathered statistical data. As an alternative, we can decide to store the data associated to only a part of the invocations performed. This could be a recommendable way of working, but the percentage of data stored must be big enough, so they can be representative of the total number of invocations.

The process of updating the statistical database must be performed in an automated way, and this automation requires that the variables used in the process can be immediately computed after a service invocation. That is, the engine cannot update a variable that represents the time spent by a provider in serving orders. Actually, variables that cannot be computed from a service invocation are usually provider-related variables, and not service-related ones. Provider-related variables should be considered as external variables, that is, user-managed variables.

Let us suppose that we have developed a client application that uses a Web service to provide a book selling service over the Internet. Let us consider two sample variables: delivering time and package quality. Neither one can be computed when invoking the service since they are provider-related variables.

Provider-related variables, as it happens with service-related ones, can be either quantitative or qualitative, so the same conversion process used in service-related variables can be applied to provider-related ones. In the previous example, delivering time is a quantitative variable, while package quality is a qualitative variable.

The evaluation process of a provider-related variable can be performed the same as the service-related variables evaluation. Actually, both types of variables can be mixed in the same expressions, because one type of variables and the other should be correctly adjusted when performing an evaluation.

However, the qualification of a provider cannot be performed in an automatic way, because the values of variables (provider-related) can be unknown during the lifecycle of an invocation. When using expressions that include provider-related variables, the VWS must have access to data that represent the behavior of the providers in previous invocations. That is, a process external to the engine must update the statistics database. This way, when the VWS engine computes an expression, it can do it without caring about the type of variables used (service- or provider-related), since all the data will be available. From the point of view of the engine, there is no difference between one type of variables and the other.

Rating Subsystem

Our virtualization architecture proposes the use of an optional "rating server" as an extra component that should be in charge of managing statistical data. That is, the rating subsystem is in charge of the qualification and the evaluation processes in the previous section. The VWS engine and the rating server could be the same machine. However, in a big production system, an independent rating subsystem could be used.

The rating system defined inside our QoS architecture is not concerned with the quality of the server nor the client, but with the quality of the services and the providers. Our purpose does not care about the way the rating server is implemented.

When the VWS engine receives an invocation request, it must send a query to the rating server in order to select the most suitable Web service provider. Querying the rating server is a process that can be performed on each invocation or periodically, depending on the VWS engine criteria. Something similar occurs when the engine needs to update statistical data on the rating server. Additionally, in order to optimize the number of accesses to the rating server, the VWS engine could store the statistical data of all the invocations and update the server only at predefined intervals using summarized information. In production environments, it can be interesting to build rating systems that do not use real data obtained from the results of the execution of services, but only sampled data, because of performance reasons.

The rating server location is a major issue. A corporate server can be used, so it will be used as a "provider repository." Alternatively, a public rating server managed by a third-party company can also be used. In this case, the reliability of the rating system will depend on the trust placed in the provider of the rating server.

APPLICATIONS: HIGH AVAILIBLITY

Cluster Implementation

A VWS document that describes a virtual Web service whose invocations can be solved by a set of providers corresponds to what we call a "cluster of Web services." By using VWS documents, clusters can be built by using engines and providers. Our virtualization model establishes the existence of two types of nodes inside a cluster. The first type is the principal node. This node will be in charge of receiving service invocation requests. We must place the VWS documents inside the principal node. The second type is the nonprincipal node or provider node, and it is in charge of executing requests received from principal nodes.

Using the method and invoke elements of the VWS documents we can establish a relation between real and virtual services. This way, we can create a cluster architecture where the cluster's principal node (a VWS engine) will be the one in charge of receiving client requests and distributing the workload across cluster nodes (Web service providers).

According to this structure, if a provider (a cluster node) fails, the VWS engine will redistribute pending invocation requests, and the operative nodes in the cluster should take charge of unassigned workload. This way, the whole cluster continuity can be guaranteed. However, there are still some problems to solve. How can we accomplish such a load balancing system? How can we deal with a planned or unplanned node outage? How can we select the most suitable provider in each moment? The next sections will provide answers to these questions.

Building a Web Services-Based Cluster

Let us suppose that we have a Web service (WS1), with a method (M1). If we want WS1 to be a highly available Web service, we must deploy it to a cluster. The deployment process requires the Web service to be deployed to each one of the nonprincipal nodes in the cluster. This way, more than one instance of the Web service can be used, and these instances can be executed at different nodes. All of them are said to be equivalent.

To get our VWS engine up and running we must create a VWS document to define a virtual Web service (VWS1) that would contain, at least, a virtual method (VM1) (it is important to note that clients do not use the VWS documents to perform the binding; they use a standard WSDL document derived from the VWS document). Inside the VWS document, we must specify how the virtual method execution should be accomplished. We need to include, at least, three XML elements inside the VWS document: a service element describing the service; a method element that describes the method we want to publish (including its input and output elements); and one or more invoke elements. These invoke elements are the ones in charge of describing how and where the method implementation must be made.

When a method execution request for the VM1 method arrives to the VWS engine, the engine must select the most suitable provider in order to complete the request. Once a provider has been selected, a real service (implementation service) will be invoked, sending it input parameters as needed. After service execution, the engine will receive the return parameters from the real service and it will send them back to the client application. For the whole cluster to run accurately, the VWS engine has to decide which provider node would be the most suitable to perform an execution. The engine should use some selection criteria in order to maximize cluster performance.

Node Selection

After the VWS engine receives a request, the engine must select a cluster node that can accomplish the invocation request. To do it, the engine will examine the content of the method element included in a VWS document describing the virtual service. Among the providers detailed in the invoke elements (included in the method element), the VWS engine will choose the best prior to each real service invocation. This concept, the best, is a concept that can change along time.

Our virtualization model proposes the use of expressions to select the most appropriate provider prior to each invocation. Each method element inside a VWS document should include an expression. This expression must reflect which the priorities are when a provider has to be selected. Let us consider Expression (6)

```
0.7*A+0.3*R (6)
```

where A is the availability and R is the response-time, and they represent historical data about a given Web service. Prior to a Web service invocation, the VWS engine must compute the values associated with all services specified in the invoke elements inside a method element, then compare all result values, and, finally, invoke the service with the highest score.

In order to unify scales, ranges, and units for all variables used in an expression, the function adjust can be used. In addition, for variables whose minimum values represent a maximum scoring, the function reverseAdjust is available. So, Expression (6) could be perfectly adjusted and rewritten like Expression (7):

```
0.7*adjust(A)+0.3*reverseAdjust
(R) (7)
```

Cluster Maintenance

To succeed in having a 100% available system, methods that allow performing maintenance on the cluster must be available. When we need to perform any kind of maintenance, we meet with the need for stopping part of the system. If we want to stop a node without interrupting activity, we should use an "upDown" variable and add it to all expressions used inside the cluster. This way, we can rewrite Expression (7) as Expression (8):

```
upDown * (0.7*adjust(A)+0.3*reve
rseAdjust(R)) (8)
```

If we want to remove a node from the cluster, we must set the value of the upDown variable to zero, and the node will stop receiving new execution requests. That is, the node enters a draining state, and when there are no pending requests, the node can be removed from the cluster.

Node Error Detection

During normal cluster operation, errors can appear that can cause two different effects: increments in response time, and fatal errors like a node outage. The VWS engine is the element in charge of dealing with those kinds of errors.

If the response time of a given node is increased more than usual, the normal operation of the engine should make that node stop being used. This can be accomplished by adding a variable called R (response time) to all expressions. For example, using Expression (7) providers with the lowest response time will always get a high qualification value, while providers with a high response time would stop being selected for an invocation. If a node outage is detected, then the VWS engine should stop invoking services on that node. To deal with this situation the VWS engine must use the upDown variable, like in Expression (8).

When does the provider be used again? A simple procedure for dealing with this situation would consist on using a polling technique (PING or repetitive TCP-open). A most appropriate method consists on having a mechanism that allows the provider to send a notification to the engine, in order to notify the new state. VWS engines must provide a Web service, including a specific method (let us name it "upDownPort" method). Using upDownPort, providers can notify its actual state. Moreover, the upDownPort can also be used to stop a cluster node (by modifying the upDown variable value).

Scalability

Scalability problems are usually solved using two different types of solutions: vertical scalability, achieved by improving hardware configuration of the cluster nodes, and horizontal scalability, where new nodes can be added to the cluster. If we decide to use vertical scalability, we will find no problems when implementing virtualization, since Web services are completely independent on the hardware infrastructure. If we decide to use horizontal scalability as a way to extend the whole cluster capacity, we must search for alternative cluster structures, when building virtual services.

Our virtualization model sees the cluster as a tree, in which the root node is the VWS engine, and the provider nodes are leafs in that tree. The first way in we can extend a cluster consists on adding leafs to the tree (Figure 5).

The virtualization model also proposes another type of scalability, that is, hierarchical scalability. With VWS, we can publish virtual Web services and use them as if they were "traditional" (standard) Web services. A virtual service implementation can be done using another virtual service, and so we can build cluster structures that contain intermediate nodes. According to this, the root node of the cluster would be a VWS engine, leaf nodes would be provider nodes, and intermediate nodes should be implemented as a mixture of both a root node and a leaf node. Intermediate nodes should behave as a root node in order to send requests to leaf nodes under it, and as a leaf node that receives requests from a root node. In Figure 5, an expansion of "Node 2" has caused the creation of an intermediate node and the addition of two new nodes.

APPLICATIONS: QOS

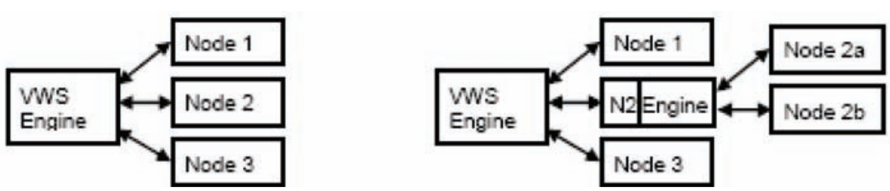
When developing software that uses Web services, things like the uncertainty associated to the Internet (e.g., unpredictable workload, uncertain and highly oscillating number of users, etc.), must be taken into account. In addition, the quality of the providers used (i.e., its availability, reliability, response time, etc.), will have a great impact on client's applications.

All the providers are different, and clients always want to use the best one. This concept, the best, is a concept that changes along time, due to network outages, server outages, high response times, and so forth. In order to use the best Web service from the best provider, we need to use systems that gather statistical information about providers and their services. That statistical information should be updated with time, so client applications always invoke the best service and provider according to that statistical data. As we have seen, our virtualization architecture proposes the use of three elements that enable the selection of the most suitable service and provider:

- A qualifying method for each one of the services and providers.
- A way to obtain historical qualifications of previous invocations.
- An element in charge of computing the qualifications and performing an evaluation using the information gathered previously.

A correct operation of the assign-and-compute-qualifications system depends directly on choos-

Figure 5. Hierarquical scalability



ing the appropriate variables, like availability, reliability, cost, or performance.

The election of the right units for the variables is a mandatory step before using a qualification system. Although there are variables like response time that can be easily measured, there are other variables like "provider security level," which are expressed using qualitative values (e.g., low level, high level, etc.). A simple way of managing the qualitative variables consists of assigning value ranges (using techniques similar to those used in fuzzy logic). This way we can map qualitative values to numeric values.

Let us suppose that we build a virtual service, and its implementation is made using three standard Web services (A, B, and C) that are equivalent (i.e., same functionality). We have decided to use the following variables to select the most appropriate service for each invocation: cost, availability, and security level. Cost is a variable whose value is established by the provider (provider-related variable), while availability and security level refer to a Web service (service-related variable).

Applying virtualization techniques to QoS problems is very easy. It only requires writing expressions that represent the QoS metrics that we want to take into account equally to the expression system we have showed for HA issues. Typycally, in clusters of Web services, we will use Web service-related variables, while in QoS problems we will use a mix of Web service provider-related variables and service provider-related variables.

APPLICATIONS: CACHING

It is possible to define at least two different caching structures in Web services architecture. The first one is a two level caching architecture (2LCA), which involves the existence of two entities: server and client. This caching architecture is not new, and caching is applied here using a typical caching implementation, like the one used by Web browsers that access Web servers directly. Three-level caching architecture (3LCA) is also possible. This kind of architecture is likely to occur in an environment where intermediate elements are an active part of the whole architecture. In a 3LCA, a third component appears, the intermediate element, which can also be an active actor in the caching system.

Our purpose is a very good solution to improve the performance of Web service-based applications, especially in stressed environments (with high volume of invocations). In addition, our purpose, far from the traditional HTTP cache system, gives a high degree of freedom to Web service developers, since our purpose, based on the use of extra information that is sent with SOAP messages (VWSEL), allows Web service programmers to control the way that messages are cached by client entities. That is, our purpose allows developers to control a cache system in a different way on each invocation, depending on the execution logic of the Web service.

There are some works on improving Web services performance by using caching; some of them are based on several different programming mechanisms. Goodman (2002) presents a solution based on the use of a cache object. This object is a Java object that must be managed from the Web service logic. This solution does not avoid network traffic, since invocation must be received at application code, in order to access the above-mentioned cache object.

Other kinds of solutions are based on the use of HTTP headers to manage the expiration of the HTTP responses. In "Perform Output Caching with Web Services in Visual C#.NET" (2003), the use of programming attributes (similar to compilation directives) is proposed. The use of the WebMethod attribute, together with the CacheDuration property, allows a simple way to control the TTL of the response. Again, this solution is based on the use of HTTP, enforcing a dependency between a Web service (and its business logic) and a transport layer (HTTP). In addition, it is a static mechanism, that is, programmers cannot control the duration of a response depending on the logic of the Web service.

RELATED WORK

Virtualization is being successfully applied to many other environments, such as storage virtualization, network virtualization, and hardware virtualization. What we propose here is to virtualice software, creating new virtual components (e.g., VWS) with which we can achieve a degree of decoupling and independence between clients and providers greater than the one we could achieve with standard Web services.

The architecture we propose is innovative as a global solution for a range of problems that have only been addressed individually so far. Problems related to SLA management, quality of service, or high availability are the subject of study by public and private entities, but the solutions proposed are specific for each one of these issues: architectures and languages to support SLA management (Dan, Ludwig, & Pacifici, 2003; Ludwig, Keller, Dan, King, & Franck, 2003; Sahai, Machiraju, Sayal, Jin, & Casati, 2002), metrics for QoS (Barry, 2003), and software and hardware architecture intended to improve the availability of the implementation of Web services, but not their interface, which is what clients perceive as a Web service. We have also discussed about these issues our 2004 work.

At the same time, the use of intermediate elements (the engines in our proposal) is a technique that is being implemented in some software platforms, but always with a specific use and using proprietary languages and/or systems. For example, WS-DBC (Brose, 2003) uses an intermediate element as a security system, while WS-Gateway (Venkatapathy & Holdsworth, 2002) isolates the private networks of clients and/or providers, also supporting certain protocol changes (e.g., from SOAP to HTTP/POST).

The work we have performed on caching systems has a close relation with the theories exposed by Cao and Irani (1997) and Cao and Liu (1997) and other works. Moreover, the same as the theories exposed by Chankhunthod, Danzig, Neerdaels, Schwartz, and Worrell (1996) and Worrell (1994), our caching purpose will add even greater benefits when applied to a hierarchic architecture, like the one we proposed in 2004, based on the use of VWS engines in charge of routing SOAP messages.

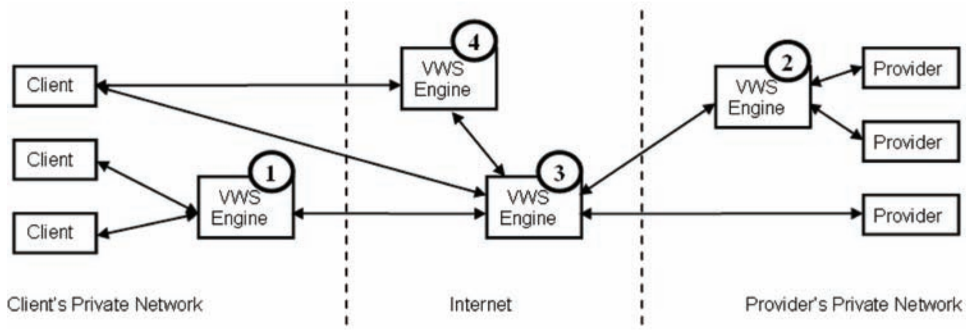
CONCLUSION AND FUTURE WORK

There exist several ways to apply the proposed architecture to the current Web services technology. Those forms represent different implementations and lead to obtaining different functionalities depending on the localization of the VWS engine. Basically, we can distinguish three alternatives, depending on whether the engine is located: (1) in the private network of the client, (2) in the private network of the service provider, and (3) in the Internet, being accessible to both client and service provider.

In case (1) above (point 1 in Figure 6), the use of an engine offers the following functionalities:

- It makes the software of the client independent of that of the delegate provider, because the engine allows both of them to change their interfaces without affecting the other, as long as the engine can map the different structures of the SOAP messages exchanged in the invocations.
- Provider independence. Virtual Web services allow the adding, modifying, and removing of providers without affecting the client, that is, without any need for the client to modify its applications.
- Proxy. The use of the engine allows client applications to invoke Internet Web services even when they have cannot connect to

Figure 6. Sample architecture implementation



anything beyond its private network.

- Automated error management. Because the methods of the virtual services are built from a list of Web service providers that is functionally equivalent, the engine can control the errors that take place and, when a provider fails, try to use another one. This occurs unnoticed for client applications.
- Cache. As we have seen, it is possible to cache client requests, noticeably improving response times. Take as an example the case of a Web service that offers share prices on the closing of financial markets, or a weather forecast Web service.

An engine placed inside the provider's private network (point 2 in Figure 6) fundamentally allows the building of Web services cluster systems, where the VWS engine acts as a controller node for the cluster, in charge of receiving requests and routing them to a certain node that is selected depending on the workload of each node (point 3 in Figure 6). Other possible functionalities are:

- Firewall. The VWS engine allows providers residing in a private network to be invoked from outside that network, keeping a high security level inside of it.
- When used as a cluster controller, it allows for the introduction of modifications in a node of the cluster while keeping the others unchanged, making it possible to perform software testing with a minimal impact in the construction of a new Web service in case of an error.

Last, in case (3) (Internet engine), its main use is that of a broker, that is, the engine acts like an intermediate component in the network that puts clients and service providers in contact (point 3 in Figure 6), moreover offering the following main functionalities:

- Decoupling between delegate client and delegate provider, due to the fact that the definition of virtual services makes it possible to modify the interface of the delegate providers (Web services) without changing the client software.
- Use of multiple providers.
- Error control and management.

What we propose is to use a common language for the description of virtual Web services, which at the same time provides a standard way to construct the interfaces that intermediate elements must offer through standard WSDL documents. We also propose an extension of the standard architecture in order to support VWS in such a way that it be compatible with current architecture.

VWS can help developing Web services with rich features like high availability, performance optimization, QoS, error management, and so forth.

The overall performance of the proposed architecture (whichever its use) will greatly depend on the variables and expressions used for the description of virtual Web services. It has to be noted that the VWS engine introduces a new overhead inside the execution architecture, since requests must be received and rerouted to the appropriate provider. However, this overhead is not significant when compared to the benefits obtained with our architecture.

Using VWS developers can build atomic Web services that can be published and subsequently consumed by resource-constrained devices like mobile phones or PDA; that is, virtual Web services can be used as a personalization mechanism regarding client requirements in order to simplify its use in such device types.

VWS technology is the base for other works that extend the use of our model. Regarding these other features of our model:

- We can use the VWS documents to build composite Web services. This work is in progress, and we are defining a set of different types of invocations. Our goal is to develop a Web services programming language (WSPL, as an extension of VWSDL) that supports basic programming structures (e.g., if-then-else, do-while, etc.). Its objective is to provide a simple composition method.
- We plan to integrate WSLA with our Web service descriptions. This way, a VWS engine can be used to analyze each invocation of a Web service and evaluate SLOs after each invocation.

Our proposal is not disruptive in its implementation, because it can coexist with the current architecture with no problems at all. Ideally, in fact, both architectures should coexist, because the standard one shall be used for easy problems in controlled environments, like the invocation of Web services in a corporate network.

Chapter 8.11
Web-Based Corporate Governance Information Disclosure:
An Empirical Investigation

ABSTRACT

Effective and timely use of the Internet, with a navigable and regularly-updated corporate Web site, can improve perceptions about a company's transparency vis-à-vis corporate governance practices. Based on an empirical analysis of data from 30 company Web sites in the DJIA, we conclude that a majority of companies underutilize their Web sites in communicating corporate governance information. Nearly all companies provide only routine content disclosure using minimal Web design features. A proactive display of compliance and due diligence content is largely absent, and most companies have yet to exploit advanced Web technologies to the fullest. Companies with better quality content and design appear to have higher corporate governance quotient (CGQ) ratings thereby implying greater transparency. The resultant framework can help companies vastly improve their Web sites by including more content that reflects due diligence and transparency and implementing Web 2.0 and other advanced technologies. Companies serious about transparency will adopt a more strategic approach to Web content and design. The lists of variables we identify can serve as checklists and/or templates for executives and researchers.

INTRODUCTION

The importance of proper governance has been underscored recently by a wave of well-publicized corporate scandals including Enron, Tyco, WorldCom and Global Crossing, to name a few. In response, firms have taken steps to strengthen their governance not only by making boards more independent but also by explicitly charging directors to enhance corporate transparency through the adoption of higher disclosure standards. Advances in information technology (IT), such as financial information systems (FIS), extensible business reporting language-enabled (XBRL) reporting, open conference-call technology, and Web 2.0 have greatly facilitated this endeavor by ensuring the timely production and cost-effective dissemination of corporate governance information. The key role of the corporate Web site, in particular, lies in facilitating communication between the public company and its stakeholders (Jones, 2002, 2003a, 2003b; Prentice, Richardson & Scholz, 1999; PricewaterhouseCoopers, 2004; Schultz, 2003).

This article draws, and merges, two streams of the literature, namely the corporate governance disclosure stream, and the role of IT in corporate governance stream (e.g., the Web) to identify and analyze the variables (features) with respect to content and design of corporate governance information on the companies' Web sites. The focus is to show prevailing Web-based mechanisms and practices and to suggest opportunities for improvement. We provide managers and researchers with a framework blueprint on the effective use of their Web sites to communicate and disseminate corporate governance information.

The rest of the article is organized as follows: First, we provide a comprehensive review of the literature in the areas of corporate governance disclosure and transparency and the use of the Web in information dissemination. Next, we describe the research framework for this study. Third, we outline our methodology and analyze the data collected. We then formulate a prescriptive framework for the proper use of the Web in enabling corporate governance disclosure. Fifth, we discuss the scope and limitations of our research. Lastly, we discuss our conclusions and suggest future research.

LITERATURE REVIEW

Background Information

Monks and Minow (2004) define corporate governance as "the structure that is intended to make sure that the right questions get asked and that checks and balances are in place to make sure the answers reflect what is best for the creation of long-term, sustainable value." Put more simply, governance refers to a body of rules and regulations that corporations must follow to protect the rights of their stakeholders (shareholders, creditors, employees, and others). A 2002 Global Investor opinion survey conducted by McKinsey & Co. highlighted corporate governance as a significant investment criterion (Bhat, Hope, & Kang, 2006). The survey found investors have higher confidence in companies with good corporate governance. Steps to meet increased public interest in governance transparency are reflected in recent governance regulations introduced by stock exchanges and regulators worldwide. The Sarbanes-Oxley Act 2002, for example, is a federal law that sets new and stricter standards for corporate governance practices in the United States (Bhat, Hope, & Kang, 2006).

Good corporate governance implies greater transparency. Berardino (2001) points out that "investors want governance that is designed and administered to protect the interests of all shareholders. They want companies to accurately disclose their financial position and business performance (SCMP, 2001, p. 12)." Thus, a major issue facing the business community is the need to increase company transparency and directors' accountability (Brooker, 2000) to meet or even exceed stakeholders' expectations.

Bushman, Piotroski and Smith (2004) define corporate transparency as "the availability of firm-specific information concerning publicly listed firms in the economy to those outside the firm, and it is conceptualized as an output from a multifaceted system whose components collectively produce, gather, validate, and disseminate relevant information." In other words, transparency is about providing the context of business operations that validates a company's financial projections, including such details as strategic plans, risk management, policies and corporate governance information specific to the company. But taking real steps toward greater transparency is not that easy exercise (Schultz, 2003). It is challenging to introduce practices that lead to greater transparency, especially when they aren't necessarily asked for. What type and/or amount of transparency will impress stakeholders but not give away too much information, such as details that might help the competition? Institutional Shareholder Services (ISS) (Institutional Shareholder Services, 2005) suggests that in order for companies to be effective at corporate governance programs they must certainly include a broad, proactive communication agenda that maximizes the effectiveness of traditional forms of communication, such as disclosures in public filings. And yet, companies must also embrace progressive practices, including accessibility to management and board members via new technology. A 2002 KPMG International report concurs and suggests broader and deeper disclosure on corporate Web sites and in annual reports. Web sites, the report states, should have a corporate governance section, which explains, for instance, procedures for getting a motion onto a proxy ballot (DiPiazza & Eccles, 2002; The Economic Intelligence Unit, 2002). In the next section we review and discuss the relevant literature on information disclosure, information asymmetry, and transparency.

Disclosure, Information Asymmetry and Transparency

There are several recent trends in disclosure regulation (Bethel, 2007) that impact the level and nature of disclosure. These trends have implications for how the Web may be used to disseminate information. The first trend in disclosure regulation is requiring firms to provide more comprehensive disclosure. The second, which has emerged over the last seven or eight years, is a shift from periodic and transactional disclosure to on-going or continuous disclosure. The third trend is a push towards broader dissemination and accessibility to information by investors. And the fourth trend is greater personal accountability by CEOs and CFOs for the quality of accounting statements (Bethel, 2007).

Disclosure regulation is usually associated with informational asymmetry or some form of externality (Healy & Palepu, 2001). When asymmetry of information exists between investors and internal management, adverse selection problems surface and bid-ask spread in securities price can widen. Not knowing the qualification of a company's true value, investors might attempt to shun the risk from asymmetry of information by overstating the discount rate on equities or risk premium on bonds (Chen & Jian, 2005). The market microstructure literature indicates that market liquidity increases as information asymmetry is reduced (Kanagaretnam, Lobo, & Whalen, 2007). An emphasis on information disclosure could eliminate such asymmetry and reduce capital and operating costs (Verrecchia, 2001).

Also, an agency problem surfaces when asymmetry of information exists between information providers and internal management. Instead of creating maximum value for shareholders, self-interested parties might opt for wasteful, privileged expenditures or overinvestment, a typical form of moral hazard cause by information inconsistency. One well-known solution to asymmetry is regulated disclosure. Both Leftwich (1980) and Watts and Zimmerman (1986) suggest that by creating minimum disclosure requirements, regulation of disclosure reduces the information gap between “informed” and “uninformed” agents in the economy. On this topic, Healy and Palepu (2001) point out that there are three reasons for companies to volunteer their corporate information: to increase liquidity of stocks, to reduce capital costs, and to gain media coverage. Other studies (Diamond, 1985; Verrechia, 2001) examined the consequences of voluntary information disclosures and concluded that such releases benefit investors. Information asymmetry declines as these public information releases “level the playing field” for all-investors (Pozen, 2006). In addition, the need for investors to engage in costly information gathering is reduced. Transaction cost theory too, suggests that greater transparency goes hand in hand with lower capital costs because of reduced transaction costs and/or reduced estimation risk (Habib, 2006). Callahan, Lee and Yohn (1997) conclude that, “by improving the information environment for companies through better disclosure, accountants can contribute to a reduction in transaction costs, and hence the cost of capital” .

Lastly, prior studies also have documented that the quality of a firms’ mandatory and voluntary disclosures both increase with the quality of the firms’ corporate governance. In the case of mandatory financial reports, better quality governance is associated with a lower likelihood of financial statement fraud (Beasley, 1996). And better quality governance is associated with higher overall level of voluntary disclosure (Eng & Mak, 2003). In summary, both mandatory and voluntary disclosures have a positive impact on the overall performance of a company.

In the next section we examine the role of the Web in governance disclosures.

Web-Based Disclosure

IT such as the Internet and the Web has great potential to disseminate corporate governance information effectively leading to better quality disclosure and improved transparency. For example, XML and extensible business reporting language (XBRL) provide financial information users with a standardized Internet-based method to prepare, publish, and exchange financial information (Boritz & No, 2005; Debreceny et al., 2001a).

Several studies have attempted to identify the determining factors of Internet-based corporate disclosure (ICD). Ashbaugh, Johnstone and Warfield (1999), Craven & Marston (1999), and Ettredge, Richardson and Scolz (2001) found that larger U.S. and U.K. companies are more likely to provide financial information on the Internet. Ettredge, Richardson and Scolz (2002) studied the determinants of voluntary ICD in the Unites States. A distinction was made between disclosure of items that are mandated by the SEC, and those not required by regulation. The findings indicated that the former are associated with company size and information asymmetry between the company and investors whereas the latter vary with company size, information asymmetry, demand for external capital, and disclosure reputation. However, the study only examined the content aspect of disclosure.

In a study of the application of the Internet in reporting among Chinese-listed companies, Xiao, Yang and Chow (2004) developed a disclosure index of 82 items based on the framework of Web-based disclosure proposed by Debreceny, Gray and Mock (2001b) with further references to other prior studies by Deller, Stubenrath and Weber (1999), Marston and Polei (2002), and Pirchegger and Wagenhofer (1999). Their index encompassed 58 items of disclosure content, and 24 items about presentation format. The content items showed what the companies disclosed on their Web sites. These included items required by the China Securities Regulatory Commission (CSRC) and non-CSRC-required items. The presentation format items dealt with how the information was presented (e.g., whether it was in processable format) and its convenience of use (e.g., whether there was an internal search engine).

A study by The Economist Intelligence Unit looked at the Web pages of the top 10 firms by market capitalization in each of five countries: the U.S, U.K., Japan, France and Germany over a three-week period in July 2002 (The Economic Intelligence Unit, 2002). Each company was assessed for the provision and accessibility of information on 29 different governance issues, including disclosure on executive pay, information on non-executive directors, retention of auditors and ease of voting at the annual general meeting (AGM). The study found most companies (two-thirds of the 50 reviewed) offered a separate and easy-to-find section on corporate governance. The exceptions were in Japan and the Unites States, where such sections were only available on half of the Web sites reviewed. Nevertheless, transparency in some areas was spotty. If, for example, one wanted a record of how often non-executive directors attended board meetings, most companies (94%) did not disclose the information, and only in two cases was one able to find the information in less than 30 minutes of searching. Governance information from CEO searches to selection of directors and auditors to shareholder voting rights typically was found either buried in or missing from the Web pages and annual reports (The Economic Intelligence Unit, 2002).

In 2002, Blunn and Co. (2003), an investor relations consulting firm, conducted a study to gauge the extent to which companies had improved their disclosure of governance information on their Web sites. The surveyors inspected the participant Web sites against the NYSE, SEC and Sarbanes-Oxley requirements for Web site disclosure. The result: Blunn found that very few companies complied with the new NYSE governance listing standards. Of the 135 companies reviewed, 84% did not have a corporate governance section on their Web sites; only 14% published their corporate governance policies prominently; and less than 25% published their companies' corporate codes of ethics (Jones, 2003a).

In a follow-up study by the same company conducted from March 3 to 26, 2003, the corporate Web sites of 250 public companies in several countries were surveyed to assess the breadth of corporate governance information disclosed online (Blunn & Co., 2003; Jones, 2003b). This study concluded there was room for improvement across the board in the breadth and depth of what companies publish online. Only 33% included at least their corporate governance policies, key committee charters and a code of conduct applicable to senior officers. Only 10% provided insider transaction information. A large number of the companies did not identify either the financial experts on the board or the audit committee nor did they provide information on their managements' internal control structure, systems or reporting processes. Further, very few companies had posted procedures for reporting accounting complaints to the audit committee. Lastly, the study showed that except for a handful of best practice companies, governance information was for the most part difficult to find on corporate Web sites. Typically, the information was buried among a variety of print documents that had been scanned and posted to sites (Blunn & Co., 2003) without attention to accessibility.

The investor relations global rankings (IRGR) is a comprehensive audit and ranking system for IR Web sites, corporate governance, and earnings release and disclosure procedures. As far as corporate governance is concerned, IRGR's evaluation criteria include only major content issues (MZ Bulletin, 2006). A recent study by the *Financial Times* assessed top-class corporate Web sites (Bowen, 2007) and concluded that the best Web pages were managed according to well-observed rules and processes. These top sites also offered high-quality service to stakeholders and provided good contact points. More importantly, they made exceptional use of Web technology, with broadband spreading, video, pod casts and other features. Missing, however, was much evidence of Web 2.0 technology and its interactive functions for building online communities (This may be because these corporate giants are laggardly or because they are rationally cautious.).

These studies have several limitations. First, nearly all of them studied content alone. By overlooking design, researchers ignored an important aspect of Web site value. Second, with the exception of the FT and IRGR studies, earlier research is outdated. Regulatory requirements and Web technology have changed dramatically in recent years. Finally, there's been an attempt to link, at least minimally, Web pages' content and design to some measure of overall corporate performance.

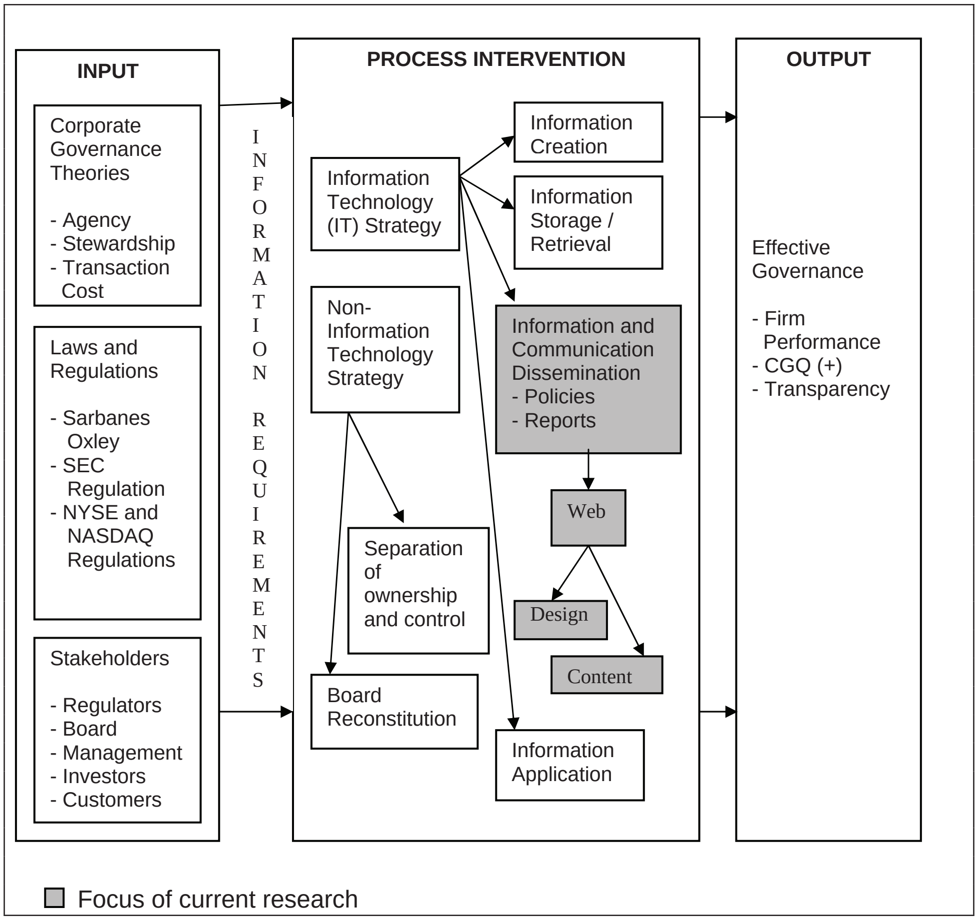
Our study revisits the question of the successfulness of corporate Web sites by looking at a more representative sample and addressing content *and* design issues. Also, we attempt to find a correlation between Web pages and a company's corporate governance quotient (CGQ) as a performance measure. The CGQ is discussed under methodology.

CONCEPTUAL FRAMEWORK FOR THIS RESEARCH

Our conceptual framework for the relationship between the Web and disclosure builds on the work of Bushman et al. (2004). They provide a framework for conceptualizing the informational environment of the firm. They classify information mechanisms in their framework into three categories: corporate reporting (e.g., Web content), private information acquisition, and information dissemination (e.g., Web design). Corporate reporting involves periodic disclosure of firm-specific information on a voluntary or mandatory basis. With regards to private information acquisition, relations between public information disclosure and the private information processing and gathering activities of investors have been recognized as important determinants of information allocations in an economy (e.g., Verrecchia, 1982). The inclusion of the third component, information dissemination was motivated by Bushman et al.'s (2004) perspective that lack of a well-developed communication infrastructure (e.g., Internet-based) may impede the flow of information reported by firms, limiting the availability of the information to economic agents. One could measure information dissemination by analyzing the content and design features of the Web sites.

Figure 1 represents a conceptual framework of corporate governance and its relationship to Web pages. The *inputs* represent corporate governance theories, such as agency theory and stewardship theory that provide a framework in which managers need to perform mindful of the interests of the stakeholders. First, typically governance is the charge of executives at the highest level. Secondly, various laws and regulations now specify financial and other procedures regarding disclosure of corporate information to shareholders, creditors, employees and others. The Sarbanes-Oxley Act and the Securities and Exchange Act (SEC) are examples of newer regulations for governance. Another input for governance is the information requirements of stakeholders (Hermansen, Hill, & Ivancevich, 2000). Shareholders, creditors, customers and employees expect access to documents that will give them an accurate view of a company's position and standing. Such documents include corporate business policies, statements, and the charge of various committees, corporate ethics, and social responsibilities, among others. These inputs are transformed by *process interven-*

Figure 1. Conceptual Framework of Relationship between Corporate Governance and Web Sites



tionists, which facilitate the execution of various tasks and enable conversion of primary inputs into the desired output, namely effective governance. The inputs have a common element in that they emphasize the flow of information to and from companies (e.g., to stakeholders). Information technology (IT), such as the Web, provides the tools and resources necessary to provide a smooth and efficient flow and exchange of information. In addition, non-IT strategies include ensuring effective governance through reconstitution of the board, separation of ownership and control and others. This focus deals with the board of directors, executives, and their activities. The IT strategy, on the other hand, focuses on intervention in four corporate governance processes involving information flow: information creation, information storage and retrieval, communication and dissemination/transfer, and application. Creation involves development of new content or replacement of existing content to make better decisions (Alavi & Leidner, 2001), such as using report generators to create reports. Storage and retrieval refers to the means by which information repositories are developed and retrieval mechanisms are set up to retrieve and utilize information. An example might be software that allows companies to store financial information in an easily retrievable format. Communication and dissemination refers to the presentation and distribution of governance information to stakeholders thereby ensuring increased accessibility and availability beyond the barriers of time and space (Alavi & Leidner, 2001). IT, (for e.g., say the Web), increases a company's reach beyond the formal communication lines in an organization. Web and pod casting, blogs, discussion forums and electronic bulletin boards are examples of Web facilities that increase and improve the diffusion of governance information. An important component of information dissemination is its relevance and timeliness.

The research in this study focuses on the use of Web pages to communicate and disseminate governance information. The desired *output* of effectively designed Web pages is a high level of corporate governance transparency. And by extension, this perception of transparency correlates with a firm's overall performance and measures (e.g., CGQ). The next section describes the methodology and data analysis for our study.

METHODOLOGY AND DATA ANALYSIS

The 30 companies that make up the Dow Jones Industrial Average (the Dow 30) were used for this study. These companies are also included in the S&P 100 and provide a fair representation of large to mid-cap companies.

We recorded the CGQ (corporate governance quotient) for each company as of March 1, 2007. The CGQ metric was developed by Institutional Shareholder Services (www.riskmetrics.com) to measure and compare the corporate governance structures of public companies. The ratings are relative and are reported on a percentile basis ranging from zero to 100%. For this study we created two groups: companies with a CGQ greater than 75% (high) and companies with CGQ less than 75% (low). We decided on this classification after reviewing the literature on CGQ available at www.riskmetrics.com. Generally speaking, companies with higher CGQ scores have better governance. A company's CGQ ratings appear on the first page of each ISS proxy analysis. Each company receives two CGQ ratings: The first score compares the company's corporate governance practices with a relevant index such as the S&P 500, the S&P (mid-cap) 400, the S&P (small-cap) 600, or the Russell 3000; the second score compares the company's corporate governance practices with its industry peers using S&P's 23 sector groupings.

According to ISS, the CGQ ratings comprise eight core topics (and 61 sub-issues), namely board structure and composition; charter and bylaw provisions; laws of the state of incorporation; executive and director compensation; quantitative factors such as financial performance; director and officer stock ownership; director education; and audit. The score for each core topic represents a set of governance variables. The eight core topics currently include six rating variables. If ISS indicates that a company's index ranking was 37.1, it means, in terms of governance, that the company had outperformed only 37.1% of the companies in the S&P 500. ISS assigns overall corporate governance grades to over 5,100 public companies, and it provides them free on the 'company profile' pages on Yahoo Finance (http://yahoo.finance.com). Due to our limited sample size, we recorded only the percentage comparison to the S&P 500.

Building on prior literature discussed in the section of Web-based disclosure, we address two categories of variables: content and design. The set of individual variables constituting 'content' and 'design' were identified based on a large literature review of previous studies, information obtained from federal laws (e.g., Sarbanes-Oxley), regulatory bodies' (e.g., SEC, NYSE, Nasdaq), and consultant/service provider organizations (e.g., Institutional Shareholder Services, Governance Metrics International). Content variables refer to the various corporate governance disclosures and documents, voluntary and mandatory, displayed on a company's Web sit (Blunn & Company, 2003; Jones, 2002, 2003a; 2003b; Institutional Shareholder Services, 2005; MZ Bulletin, 2006;

Table 1. Descriptive Statistics for Content – CGQ

	Group1 (n=16) (CGQ > 75%)		Group 2 (n=14) (CGQ < 75%)		Total (N=30)

Schultz, 2003). The individual and composite content variables are listed in Table 1. Typically, past studies have looked only at content issues. In this study we also look at various design variables listed in Table 2. The design variables were also grouped into composites, each characterizing a certain theme. Using company home pages as starting points, two researchers collected content and design information by independent manual inspection. This is consistent with how content analysis is performed. Differences were reconciled by re-visiting the Web pages. We looked for the presence or absence of each content variable and coded it in binary format (1=present, 0=not present). Likewise, the presence or absence of each design feature was recorded. The data was summarized and tabulated to develop frequency counts and percentages for the two CGQ groups. Composite percentage scores were also calculated to obtain a big picture view. Apart from the independent study and findings of the content and design variables, we also wanted to identify correlation between content, design and a company's CGQ.

CONTENT

Table 1 summarizes the descriptive statistics for the corporate governance content features grouped by the two CGQ categories of companies. This classification provides a basis for comparing the content vis-à-vis the CGQ. A composite picture of the corporate governance content is the result.

Board

In this group of variables, only four companies provide information on the duties and responsibilities of the lead director position (13.3%). For the related variable of independent director information, only seven companies were found to display that information (23.3%). A majority of companies (53.3%) provide a direct link to contact directors/board. Further, 80% (n=24) provide director biographies, and an overwhelming number of companies, (n=28) 93.3%, display information on committees they serve. Only 11 companies (36.7%) give any information regarding director compensation. It's interesting to note that more companies among the higher CGQ group provided director compensation information than in the lower CGQ group.

Committees/Charters

All companies provide information about their audit committees, and an overwhelmingly majority devotes online space to their compensation (n=28) and governance (n=29) committees. However, correlated to lead director information under "Board," only two companies (6.71%) provide the charter of the lead independent director. Surprisingly, only 50% (n=15) give information on the all-important executive committee, and 20% (n=6) specify the financial experts on the audit committee board. Sixty percent (n=18) provide information on the nominating committee. Furthermore, at least two companies with CGQ > 75% gave the charter of the lead independent director. None of the companies with CGQ < 75% did so. Additionally, 75% of companies with higher CGQ provided information on the nominating committee compared to 42.9% of companies with lower CGQ. There is, then, scope for communicating additional committee/charter related governance information in this group of variables.

Compliance Policies

Overall, companies have a poor record for giving structured, visible information when it has to do with compliance. Only 13.3% (n=4) give insight into how to report accounting abuses, explain whistle blower policy & procedures or describe the role of an ombudsman, and all of these companies had CGQ > 75%. Only 23.3% of the companies (n=7) give information on the procedures to report accounting issues to the audit committee. Obviously, companies need to do a better job of providing appropriate information on compliance.

Ethics

The variables here are indicative of ethical issues related to corporate governance. While a good number of companies (n=26, 86.7%) have a code of business conduct and ethics, only 40% (n=12) declared political donations. Thirty-six point seven percent (n=11) indicated a code of business conduct/ ethics for the board and executives in particular. Companies might consider using their Web sites to make ethics policies more transparent.

Governance Documents

This important group of variables relates to a number of mandatory requirements of Sarbanes-Oxley, SEC, NYSE and Nasdaq having to do with the display and dissemination of important governance related documents. Seventy-three point three percent (n=22) of companies give the articles/certificate of incorporation /bylaws information while all companies do provide their corporate governance guidelines and principles. Additionally, 93.3% (n=28) give at least some information on securities transactions by directors and officers. However, insider transaction details are not given. This blurred view, along with the need to inform about stock option/ownership (only 6.7%, n=2, give this information), shows there is room for significant transparency, especially considering the recent buzz about stock options. It is also worthwhile to note that 37.5% of companies with CGQ > 75% give director/ executive stock option information while only 21.4% (n=3) of CGQ < 75% do so. Fifteen companies with high CGQ have some form of analyst/investor conference call, and 11 companies with low CGQ indicate this feature.

Management Teams

While 73% (n=22) provide biographies of the management team, only 20% (n=6) give information on executive compensation guidelines. Also 31.3% of companies with CGQ > 75% give this information while only 7% of companies with CGQ < 75% do so.

Press Room

All companies satisfy the basic requirement of providing press releases.

Proxy

While 93.3% (n=28) of companies have a link to the proxy statement, only 46.7% of the total set the proxy in an interactive format. Companies can use advanced Web technologies such Web 2.0 to disseminate proxy information more flexibly.

Social Responsibility

Lastly, a large number of companies (n=25) have a dedicated section on social responsibility which is tied to overall corporate governance.

Summary

Overall, with respect to content and with the exception of a few variables, there appears to be no significant differences between companies with high CGQ and companies with low CGQ. This may imply that companies with low CGQ have structural governance problems that cannot be addressed simply by displaying content on their Web pages. It is quite possible that a majority of companies provide basic content and follow basic benchmarks for what content to display on their Web pages. It is also conceivable that most use one or two Web application providers who use standardized templates. The data and analysis clearly show deficiencies and areas where companies can improve and move forward to the next level of communication and dissemination.

DESIGN

Table 2 summarizes the frequency counts and percentages for the design-related variables we identified. These are grouped by high and low CGQ companies. The data speaks for itself. A majority of companies have used basic Web design capabilities and features such as charting/analysis, multiple formats download, email alert sign up, software download support, search box and Web cast archives. But a wide range of useful tools, such as advanced Web technologies like blogs, pod casts, RSS feeds, and pop-up surveys, will do much to improve the ready availability of content on corporate sites.

Interactivity

The group of variables in this composite looks at features that make the corporate governance Web pages dynamic. While a majority of companies have charting/analysis capability at 86.7% (n=26), multiple download format (80%, n=24), e-mail alert sign up capability (83.3%, n=25) and software download support (80%, n=24), very few have blogging capability at 10% (n=3). Some have online request form feature (56.7%, n=17) and e-mail link from corporate governance page (53.3%, n=16). An effective feature more companies should consider is a pop-up online visitor satisfaction survey that assesses visitor satisfaction with corporate governance information. Only five companies with CGQ > 75% and only two with CGQ < 75% presently have this feature. Slightly more companies with high CGQ have charting capability and email alert features.

Location

This is an important variable indicating how easy (visible) or difficult (multiple levels/links) it is to access corporate governance information. Surprisingly, only 33% (n=10) of the companies have corporate governance links on their home page. For many companies, the visitor must dig down several levels (clicks) to access the information. Companies may consider elevating corporate governance to the main page to facilitate more effective dissemination.

Multimedia

In this important category, variables represent use of more advanced Web technologies. Again, this is an area companies should put to greater use more than they have been. A mere 33.3% (n=10) of companies utilized pod casting. Simultaneously, only 46.7% (n=14) of companies have RSS feeds and only 23.3% (n=7) of companies enable Web cast access without registration. Freely available Web casts clearly are less cumbersome. On the positive side, all companies employ a Web cast archive feature.

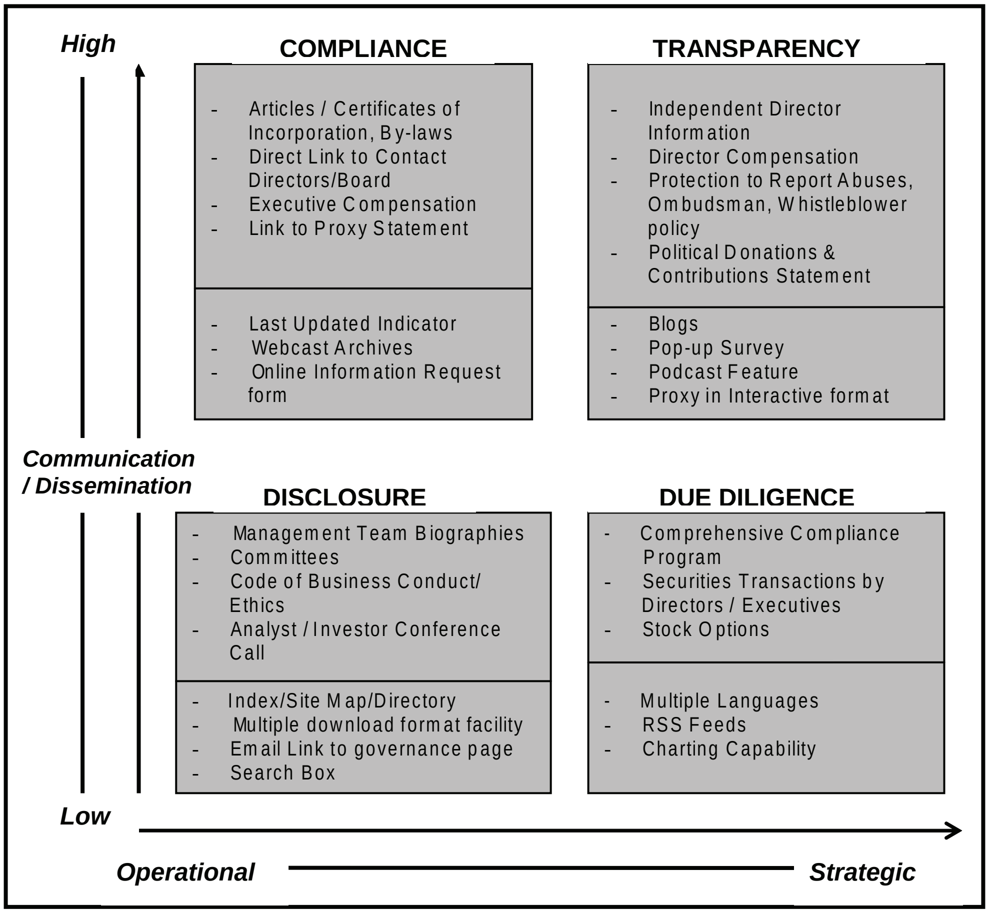
Navigation

Another critical category of design is navigation. Nearly all companies had a search box (n=29, 96.7%), while only 36.7% (n=11) of the companies had capability to view some of the corporate governance information such as ethics and governance principles in multiple languages. This was a puzzling discovery since many of the companies have a global presence. Also, only 46.7% of the companies (n=14) had a last-updated indicator. Because currency and timeliness are critical to corporate governance, companies might consider updating to include this feature. Lastly, 70% (n=21) companies had some kind of index/site map or directory. This important feature would help visitors guide through the vast amount of governance information. Slightly more companies with higher CGQ have these features compared to companies with lower CGQ.

FRAMEWORK FOR CORORATE GOVERNANCE AND WEB PAGES

While this research does not claim predictive capability, we developed a prescriptive framework based on analysis of the data. Boards of directors

Figure 2. A matrix framework for corporate governance and Web sites



and executives can use this framework to assess the present and future potential of their corporate Web sites to enable communication and dissemination of governance information and processes.

Figure 2 is a prescriptive framework of the role Web sites play in communicating and disseminating corporate governance information with the goal of greater transparency. Essentially, the X axis is a continuum from operational to strategic focus for the company while the Y axis is a continuum from low to high communication and dissemination. The resulting matrix has four quadrants. The lower left quadrant represents content and design features indicative of primarily mandatory disclosure items of corporate governance. This is the minimum functionality that a company's Web pages should possess. Primarily, static information is displayed via the links. Examples of content features include management team biographies, code of business conduct/ethics and others. Standard design features include index/site map/directory, multiple download format facility and a search box. As we progress up and the focus shifts to compliance with regulations, there's increased interactive communication and dissemination. Some of this increase is mandated, some is voluntary. It appears, based on our analysis above that most companies today would find themselves in one of these two quadrants. In the compliance quadrant, we see companies providing additional content information, such as articles/certificates of incorporation and by-laws, executive compensation, link to proxy statement and others. Design features are more advanced, with the use of Webcast archives, as well as the provision of an online information request form. A last-updated indicator feature, while simple, is a powerful feature indicating timeliness and recency. The activities in these quadrants are operational, structured and tangible and nowadays are considered routine. They are also mostly reactive (e.g., to regulation). As a company moves to the right on the continuum the goal is to enable sophisticated due diligence and achieve greater transparency. The company engages in outreach programs to connect with stakeholders proactively. Companies in the lower right quadrant are concerned with activities relating to scanning the environment, actively seeking information on corporate governance as well as contributing to industry benchmarks and standards. In terms of content, the company proactively seeks to disclose securities transactions by directors and executives as well as provide information on stock options. Important design features include a multiple languages option, RSS feeds and dynamic charting capabilities. This quadrant focused on performing effective due diligence.

For a company whose scope puts it in the upper right quadrant, the key strategic objective is greater transparency and perception of effective corporate governance. This indicates sensitivity to stakeholder needs and objectives. Strategic value is obtained by involving a stakeholder in the governance process. For example, a company can use interactive blogs and pod casting for ongoing conversation with shareholders. Additionally, proxy information is provided in an interactive format. The company lays out clearly whistleblower policy and anonymous reporting of malfeasance. For example, a Web-based anonymous reporting tool can be designed. Further, lead director information and director compensation can be disclosed.

By no means are the four quadrants boxed and isolated. Rather, they are connected and interrelated as companies evolve, moving from the bottom left to the top right. The implementation and effective use of Web pages is not a one-shot deal but a continually evolving and progressive initiative, as new requirements and advances in technology are assimilated (Pozen, 2006).

SCOPE AND LIMITATIONS

The focus of this paper is the study of Web disclosure practices of the 30 Dow Jones companies. We examined various governance-related content and design features found on the companies' Websites and compared the disclosure differences between the high and low CGQ groups. Specifically, we studied the online disclosures of corporate governance-related information. It is beyond the scope of this study, however, to explain the rationale behind a firm's disclosure practices. Nevertheless, we can suggest several insights that may explain why companies do not take advantage of Internet technology to make full and effective online disclosures.

First, concerns about the costs of compliance have been expressed in the popular press (Akhigbe & Martin, 2006; Roberts, 2004a, 2004b; Solomon & Bryan-Low, 2004). Compliance with SOX regulations requires significant, non-recurring investment costs "upfront." These include costs of building and maintaining governance Web sites. Ashbaugh et al. (1999) found that the average cost of Web site development by U.S. firms was 3.8% of the firms' total assets. Even those Web sites already in place require expertise and resources for periodic updates. According to Ghose (2006), a survey of 224 public companies by Financial Executive International (FEI) in July, 2004, found that the average cost of complying with section 404 was approximately $4 million, and that the average cost varied with firm size.

Second, disclosure of information may be costly because it weakens a firm's competitive position and reduces firm value. Verrecchia (1983,

1990) contended that firms do not fully disclose information when doing so entails proprietary costs. Bamber and Cheon (1998) provided evidence supporting this view. They demonstrated that companies with high proprietary information cost (i.e., those with few competitors) disclose less precise management earnings forecasts. Botosan and Stanford (2005) also found that firms withhold segment information when proprietary costs are high. Thus, it is unclear whether better corporate governance will enhance in every case the quality and frequency of information released by management, and/or that it will reduce information asymmetry (Kanagaretnam et al., 2007). Hence, although providing high quality financial reports was shown to reduce information asymmetries as well as the cost of capital, many firms decide against maximum reporting because of the proprietary nature of many disclosures (Habib, 2006). Chen and Jian (2005) discuss the 'lemon problem' of information disclosure as a result of conflicts of interest and asymmetry of information between internal management and external investors. Improperly-handled disclosure may fail the capital market mechanism (Akerlof, 1970). These issues warrant further research but are beyond the scope of this article.

Last but not least, while Web-based disclosure has its benefits, there are some disadvantages compared to old-fashioned hard copy corporate reporting. For one, there is the potential for information overload (Debreceny, Gray & Rahman, 2002). Also, the non-regulated nature of the Web can make controlling the context of online information difficult. Information found online can easily be taken out of context and used unfavorably by third parties. In turn, this lack of control can give rise to security and trust issues (Boritz & No, 2005). The existence of both advantages and disadvantages indicates that not all companies necessarily will benefit from Web-based disclosures.

In terms of limitations, the scope of our findings is limited by the size of our sample. A larger sample size may help generalize the results more effectively. We followed prior research in the development of the content and design templates. A survey of CIOs and other executives in charge of corporate governance may allow further insight into the role of IT in general and the Web in particular in enabling governance. This data will also enable more advanced statistical analysis. We examined the data on the corporate Web sites, and so the quality of our results is only as good as the presented data. In this exploratory work we looked at only classification variable, that is, CGQ. Consideration of such variables as corporate culture and IT acceptance in that culture, company sector (e.g., manufacturing or service), company size, and so on may have an impact on Web usage.

CONCLUSION AND FUTURE RESEARCH

Although our research is limited to the Dow 30 component companies, the sample is representative of large cap companies in the S&P 500 and Fortune 500. The findings have important implications for the use of corporate Web sites in the presentation and dissemination of corporate governance information. This impacts transparency in general.

Our analysis and results present a mixed picture. While companies in our sample use their Web sites to present corporate governance related information, they do so in the most basic (read: limited) way. In most cases, advanced content and design features are absent or found lacking. Companies have a long way to go to take full advantage of the Web and related technologies to effectively organize, present and disseminate corporate governance information. These technological enhancements would enable companies to be more transparent and thereby satisfy stakeholder needs for timely and quality corporate governance information.

Presently, the rules of the NYSE regarding Web site requirments are narrowly-focused minimum standards designed for all companies. As such they ignore some issues important to investors. They also do not provide guidance on *how* the information should be posted online. This leaves a lot of room for companies that are serious about being transparent to stand out from their peers by adopting best practices in how and what they publish online. Good disclosure of corporate governance principles reduces stock price volatility because stakeholders know their company is trying to do the right thing. Further studies with larger samples may reveal additional patterns. One might note, for example, vast cultural differences in a future study of multinational companies. Additional empirical work can provide insight into the relationship between effective communication (via the Web) and higher governance ratings. Another area for research is the examination of IT's role in enabling corporate governance by reducing the transaction and agency costs (Strebel, 2004). The use of the Web and other IT types in enabling corporate governance is in a primitive stage compared to other areas, but the use of the framework and templates developed in this article can accelerate their maturing process.

Chapter 8.12
Using Web Service Enhancements to Establish Trust Relationships with Privacy Protection:
(Extended and Invited from ICWS 2006 with id 47)

ABSTRACT

The lack of effective trust establishment mechanisms impedes the deployment of diverse trust models for web services. One issue is that collaborating organizations need mechanisms to bridge extant relationships among cooperating parties. We describe an indirect trust establishment mechanism to bridge and build new trust relationships from extant trust relationships with privacy protection. Another issue is that a trust establishment mechanism for web services must ensure privacy and owner control. Current web service technologies encourage a service requester to reveal all its private attributes in a pre-packaged credential to the service provider to fulfill the requirements for direct trust establishment. This may lead to privacy leakage. We propose a mechanism whereby the service requester discovers the service provider's requirements from a policy document, then formulates a trust primitive by selectively disclosing attributes in a pre-packaged credential to negotiate a trust relationship. Thus the service requester's privacy is preserved.

INTRODUCTION

Web services facilitate collaborations and interoperations between business partners, software agents, service providers and consumers, which promote loosely coupled and dynamic service-oriented architectures. But they do not address the business aspects of interactions such as security, access control, business partner selection, service level agreement monitoring, and auditing – the activities that build trust between a consumer and a provider of a web service and that will ultimately determine which services are used and which are not. The issues of trustworthiness are tightly bound in the minds of consumers. For example, a consumer would generally trust the Citibank online services to conduct online banking in a secure and responsible manner, because Citibank has a massive physical network of banks and has been in the financial market over one hundred years. On the other hand, a consumer probably wouldn't entrust his/her savings to a newly launched financial institution with no obvious connections to any legitimate business. The point here is that as web services begin to gain a foothold in electronic business, critical services will probably be limited to extensions of pre-existing business relationships with already trusted companies.

How can a business service provider engender new trust or transfer trust to a new consumer via an existing agent? And how can two companies establish a trust relationship in order to provide and consume business services or share information over web services? They have to negotiate in order to establish a conventional business trust relationship, and so they would almost certainly want to do the same for a trust relationship using web services. Web service standards UDDI (Atkinson, 2003), WSDL (Christensen, 2001), and SOAP (Box, 2000) say nothing about this. Thus, although it would be possible to find a web service to use just by examining a UDDI registry, it is unlikely to be used prior to investigation of its reputation and reliability. To establish a trust relationship, the consumer and the service provider require a negotiation process. The negotiation process needs to exchange trust-related information between the two parties. The parties can exchange private attributes to build the trust relationship directly, or they can use pre-established relationships to build a new one via a trusted third party. Exchange of private attributes may put the privacy of the consumer and the service provider at risk. For example, a hacker may pretend to be a consumer to access useful information from the service provider. More seriously, a hacker can pretend to be a service provider to gather private attributes from consumers for malicious usage. We need to reduce that risk. As an alternative, using pre-established relationships may be a more convenient and more secure way.

To provide additional functionalities for security, privacy and many other purposes, "web service enhancements" appear. Web service enhancements are a series of specifications describing security, privacy and other contexts applied to web services by several industrial practitioners. In this article we describe an indirect trust establishment mechanism using web service enhancements for bridging extant trust relationships to produce new trust relationships. Using an exchange of privileges obtained from a commonly trusted third party (who has established trust relationships with both parties) avoids disclosure of any private attributes. Meanwhile this mechanism still allows free negotiation and trust agreement selection between the involved parties when subjective judgments have to be made. We also propose a privacy protection mechanism that reveals the minimal number of attributes necessary to build the desired trust relationship for the web service environment. Using this mechanism, a set of attributes signed by the service requester's digital signature is associated with a trust primitive element. This element is used to negotiate a trust relationship. Any changes of policy requirements associated with this trust relationship are dynamically enforced using a trust group element. The Related Work section provides an overview of related work. The next section, Using Web Service Enhancements To Bridge Trust Relationships, describes how to use web service enhancements to bridge extant trust relationships. The Privacy Protection In Indirect Trust Establishment section introduces privacy protection in the proposed indirect trust establishment mechanism. The Using Web Service Enhancements To Protect Privacy For Direct Trust Establishment section describes a proposed parallel mechanism for privacy protection in direct trust establishment. The Prototype System section illustrates an implementation of these mechanisms in a context of healthcare applications. The Discussion section discusses the performance of the proposed mechanisms and a case study. The article concludes with contributions and future work.

RELATED WORK

Several types of trust establishment mechanisms have been described in the literature for service-oriented computing and cross-domain applications. The most basic way is to map the identity of the service requester (or one identity in the service requester's security domain) to one identity in the service provider security domain. Other extant trust management systems build trust relationships between different security domains using the requester's role as a basis for mapping. More recently, group-based mechanisms have been proposed to build trust relationships.

While "role" is an abstract concept, in a complex organizational setting such as a healthcare environment one might assign differing roles, and hence differing access permissions, to physicians, technicians, and patients. In Sandhu, Coyne, Feinstein, and Youman's (1996) article on role-based access control, role-based trust establishment process is implied by setting a mapping between local roles and roles within remote domains, which we call a role-to-role mapping. In Chadwick, Otenko and Ball's article (2003), the authors propose using X.509 certificates to manage trust relationships. This trust establishment process also employs a manual configuration of static role-to-role mappings to form a trust relationship before an actual access occurs. In the mechanism proposed by Freudenthal, Pesin, Port, Keenan and Karamcheti (2002), predefined trust relationships are used to complete the trust establishment process for dynamic cross-domain environments. The common approach of (Sandhu et al., 1996), (Chadwick et al., 2003), and (Freudenthal et al., 2002) is that the authors try to decide whether to grant access at run-time by deciding what permissions each requester has according to the assigned role and the predefined trust relationship associated with that role. The use of role as a basis for trust establishment creates a problem in domain-to-domain interactions, which is the potential misalignment of the precise definition of roles from one domain to another. One consequence could be that the domain whose users are requesting access might legitimately need to create special roles that map more precisely to the agreed intent of the requested operation. In that case, the users would be enabled by the policies of the domain they are accessing to take actions beyond those allowed them by their own domains' policies. A more general problem with roles is that their use generally does not conform to the principle of least privilege, as promoted by Schneider (Schneider, 2003), which limits the security privileges to actual needs.

Vandenwauver, Govaerts, and Vandewalle (1997) use group-based mechanisms to describe a collection of security requirements agreed to by the administrators for a group of domains. This group-based mechanism reduces the administrator's burden of creating an explicit policy to manage each trust relationship. The authors also assume that a recognized consortium of group members has created a trust group with predefined membership requirements. The service provider has to verify some non-identity attribute information about each service request. This trust group mechanism lacks the process of negotiation before building a trust relationship. Li, Mitchell, & Winsborough (2002) proposes an entire trust management framework that can group logically related objects so that permissions about them can be assigned in one operation. These logical groups are defined by an authority, not via a negotiation process. Both group-based mechanisms mentioned above require some superior authority to create or predefine group information, and thus the resulting trust establishment mechanisms are not fully dynamic; they may not keep pace with the changing policies and requirements of the service providers.

Using indirect mechanisms to bridge extant trust relationships is a convenient and efficient method to produce new trust relationships, but very few indirect trust establishment mechanisms have been designed for a web services environment. However, several types of indirect trust models and the corresponding trust establishment mechanisms have been proposed for service-oriented computing (Papazoglou & Georgakopoulos, 2003), which are the foundations of web services. The trust relationships involved in the interactions between web services are enabled by separate authorities issuing security tokens (A Joint White Paper, 2002), which certify the identities or other non-identity attributes for the requesters or providers of web services. There are two major types of trust models for these trust relationships. One type is the centralized model and the other type is the distributed model.

In centralized trust models, a common trusted intermediary, called the "Trust Authority," is used for establishing trust relationships between any two entities. However, it may be difficult to find an ideal central authority if the community of trustees is large and heterogeneous. If a trust authority is determined, token recipients are typically able to ascribe a sufficient level of trust to a security token because they can be confident of its origin. For example, they know and trust the authority that issued the token and can verify the token's origin through cryptographic means. It is through the existing trust they have in the third party security token issuer that they are able to derive indirect trust for the holder of a security token created by the same issuer. The Privacy Enhanced Mail (PEM) certification (Kent, 1993) assumes that everyone in the world trusts one ultimate authority to verify the identities of other certificate senders (an assumption we find unrealistic). The PEM model does not allow for multiple levels of trust within its certification hierarchy. Unlike PEM, the X.509 authentication framework and its variant for web services (Hallam-Baker, 2004) follows a multiple trust authority structure. It postulates that everyone will obtain certificates from an official certifying authority (CA). The CAs are organized into a global hierarchy of certifying authorities. All users within a "community of interest" have keys that have been signed by CAs with a common ancestor in this global hierarchy, which forms a tree structure.

In distributed trust models, a static or dynamic web of trust is woven with less structured logical interactions between networks (Dimmock, 2004) compared with the centralized trust models. It is assumed that trust is transitive under certain contexts, because trust-related information can be propagated through one or more chains of trusted intermediaries in the networks. In the Pretty Good Privacy (PGP) system (Zimmermann, 1995), an entity generates a public/private key pair. Each entity is responsible for acquiring the public key certificates needed and for assigning degrees of trust to their source. There is no common ancestor to act as the trust server for grouping the users within a community of interest. Instead, trust is propagated through chained structures formed by individual entities. When comparing X.509 with PGP, it has been pointed out that the most apparent difference is the architecture (Josang, 1996) (Ellison, 1999). X.509 has hierarchic structures for professional or government organizations with liabilities, whereas PGP has anarchic structure based on informal relationships and undefined roles. Like the logic-based systems described in (Rangan, 1992) (Abadi, 2003) (Pimlott & Kiselyov, 2006), there is no partial trust (degree of trust) in this kind of system; trust is either complete or nonexistent. In the solution proposed by Tarah and Huitema (1992), in the degrees of trust from different entities could have conflicts, and the final degree of trust needs to be composed from different trust values (Damiani, Vimercati, Samarati, & Viviani, 2005).

Yet none of the above frameworks or systems can accommodate all trust models. However, all the trust models co-exist in the real world and all the trust models are used in daily life. So a flexible framework to accommodate all these trust models is desirable. Other associated questions remain open, for example, the actual meaning of a trust value and how different trust values can be combined to yield a composite value. Users generally prefer to control their own private information. But none of the above mechanisms address privacy issues, which could lead to information leakage during the propagation of trust-related information in direct and indirect trust establishment processes. To solve these issues, we introduce an indirect trust establishment mechanism using a bridging protocol to augment direct negotiation and establishment of trust. We use an alternative method to supplement indirect trust establishment with lightweight negotiation to provide owner control in the process of bridging extant trust relationships. At the same time, to guarantee privacy protection, we use privileges granted by a common third party as a substitute for exchanging private attributes during the trust negotiation. Parallel in direct trust establishment, all the identity-based, role-based and group-based mechanisms do not address privacy issues, which could lead to superfluous information disclosure during the trust establishment process. We propose a privacy protection mechanism for trust establishment, which maintains the idea of negotiation but without inadvertent disclosure of unnecessary information.

USING WEB SERVICE ENHANCEMENTS TO BRIDGE TRUST RELATIONSHIPS

Web Service Enhancements

Web services use SOAP to exchange information over the network. SOAP is a lightweight method for exchanging structured information in a decentralized environment. XML (eXtensible Markup Language) is used in SOAP to define a flexible messaging framework that can exchange a message over a variety of underlying protocols. Although SOAP is the basic infrastructure for information exchange between web services, it does not provide any privacy and security mechanisms for the information exchanged. To provide privacy, security, trust, and other functionalities for web services, web service enhancements are proposed.

Among this set of enhancements, the web service security specification requires that an incoming access request message prove a set of claims such as name, public key, permission, capability, or an existing trust relationship to guarantee security. A web service indicates its requirements and other security related information in its policy document together with the privileges to be granted for the entities satisfying these requirements (e.g., a WS-Policy file). If an access request arrives without having the required proof of claims, the service provider ignores or rejects the request. These claims are contained in security tokens. A security token is a representation of security-related information conveyed within the format of a SOAP message (Bajaj, 2004). If an issuer cryptographically endorses a security token, the token is called a signed security token. A security token service (STS) is a web service that issues security tokens (Rangan, 1992). That is, it makes assertions based on evidence that it trusts to whomever trusts it. To communicate trust, a security token service requires proof, such as a security token or a set of security tokens, and issues a new security token with its own trust statement (note that for some security token formats this can be just a re-issuance or co-signature). Another important related service is the attribute service. An attribute service is a web service that maintains attribute information about entities within a security domain.

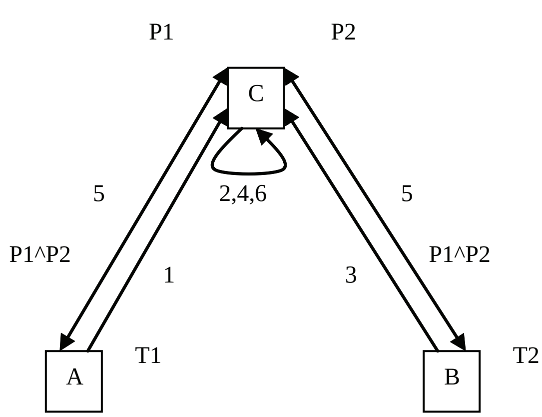
With these services one entity can rely upon a second entity to execute a set of actions or to make a set of assertions about a set of subjects or scopes (Anderson, 2004), which is called trust establishment. Trust relationships can be established by exchanging private attributes or bridging existing trust relationships; these techniques focus on owner control and utilizing extant trust relationships respectively. We propose a new indirect trust establishment mechanism to incorporate owner control into the process of bridging extant trust relationships.

A Bridging Protocol

The proposed indirect trust establishment mechanism uses a common third party as the anchor to bridge two extant trust relationships. The central part of this mechanism is a bridging protocol. An extant trust relationship is represented as a trust group element, which includes a trust relationship name (T), a list of participants involved in this relationship, and a list of privileges (P) granted for that relationship. This trust relationship can be established via an on-line trust negotiation or a contract written on paper. In the bridging protocol, the common third party needs to discover any difference in privileges granted to the two participants in order to provide the two participants equal standing and the opportunity to make their own subjective decisions for the new trust relationship. Figure 1 shows the workflow of the protocol to establish a new trust relationship between A and B using extant trust relationships between A and C, and B and C. The step numbers of the protocol correspond to the numbered arrows in Figure 1.

1. *A sends to C a request to establish a trust relationship with B, using an extant trust relationship (T1) with C.*
2. *After C receives A's request, C waits for a similar request from B. If a time limit expires, C sends a fail message to A and exits its waiting state.*
3. *B sends to C a request to establish a trust relationship with A, utilizing its trust relationship (T2) with C.*
4. *After receiving the requests from both A and B, C compares its granted privileges P1 and P2 for T1 and T2, and calculates the intersection of P1 and P2 (P1^P2).*

Figure 1. Workflow of the bridging protocol



5. *C sends P1^P2 to A and B, and asks whether they agree to build the new trust relationship based upon common privileges P1^P2.*
6. *If both A and B respond with a positive answer, C sends confirmations to both A and B. Both A and B produce corresponding new policies for the newly established trust relationship, and create a new trust group element to represent this trust relationship. If either A or B rejects the privileges represented by P1^P2, C asks A and B to establish a trust relationship directly by mutual identity verification or private information exchange. The new trust group element contains a name for the new relationship, a list of participants within this trust relationship (here A and B), and a trust level decided by each participant. So the copies of the trust group element kept by A and B contain the same name and participant list, but have their own trust levels associated with this trust relationship.*

This protocol resolves two problems introduced in the Introduction. First, it introduces a lightweight negotiation process into the indirect trust establishment (bridging extant trust relationships), which assumes that every participant has the right to make its own decisions. Second, it prevents privacy leakage by exchanging privileges granted by the common third party instead of exchanging private attributes.

The Common Third Party

How to find an appropriate common third party is also an issue. The participants A and B need to exchange partner information to find out which one is appropriate for a common third party. As with most companies, A and B's partner lists should be expected to represent private information. Companies are generally unwilling to reveal their business partner lists to companies who have not already established a trust relationship. To solve this problem, we propose a complimentary protocol below to find all common third parties.

1. A and B send requests to all their trusted partners respectively, to ask if they are willing to act as the common third party.
2. Only participants who are both A and B's trusted partner receive requests from both A and B. If a participant agrees to act as the common third party, it sends a message indicating its willingness to A and B.
3. From all the candidates who send back their willingness, A and B choose one as the common third party.

Either A or B can express its willingness to use one of the commonly trusted parties. The potential partner either agrees or starts a brief negotiation to establish the common third party before the trust establishment process with indirect privacy enhancement.

PRIVACY PROTECTION IN INDIRECT TRUST ESTABLISHMENT

Trust Establishment

Trust establishment is the initial step towards trust management over multiple security domains. Its importance has been addressed since 1994 (Beth, Borcherding, & Klein, 1994). To establish a trust relationship among multiple parties effectively and efficiently, a dynamic and flexible trust establishment mechanism must be developed (Reiter, 1999). Most existing trust management systems establish trust relationships via a trusted third party and they are based on public key certificates in which the trusted third party signs a specially formed message certifying the identity associated with a public key. The two best-known certificate systems are those of PGP and X.509. They attempt to solve part of the trust management problem of finding a suitably trustworthy copy of the public key of someone with whom one wants to communicate. This common trusted third party solution may result in a tree structure of all involved parties.

Some other existing systems try to weave a web of trust instead of a tree structure. In this case, the direct trust establishment mechanism becomes the most basic building block. The simplest way is to map one identity in a security domain to one identity in another security domain. Some other extant trust management systems also establish trust relationships with other domains using roles as a basis for mapping. And more recently, group-based mechanisms have been proposed to establish trust relationships. We will identify issues related to privacy protection in direct and indirect trust establishment processes, and provide solutions for privacy protection using web service enhancements in an interconnected and federated network environment.

Privacy Protection

Privacy protection technology consists of various tools for various applications, which includes cryptographically secured protocols for on-line critical information transmission, digital certificates, cookie management software, privacy policy languages, and so forth. Meanwhile, various anonymity protection techniques are being developed such as mix cascades and anonymous authentication for peer-to-peer networks. There are also privacy protection techniques proposed for data mining and database queries, as well as enterprise privacy auditing and enforcement tools for user privacy preferences. Privacy protection for trust establishment has particular relevance to the provision of owner control, pseudonymity or anonymity, and proof of knowledge.

- Owner control: Control over identity, credential, and private attribute information must be given to the owner, and users can modify or erase information if desired. Also, the security domain administrator does not endorse any disclosure of any piece of the user's private information. The choice of attributes to be disclosed is entirely under the owner's control.
- Pseudonyms and anonymity: The holder of the pseudonym can prove ownership by forming a digital signature using the corresponding private key. Such keys could be bound to attributes within digital certificates to form attribute certificates. One can also uses of a trusted third party to act as a mediator, vouching for the user or his/her computing device but removing any information identifying the user.
- *Proof of knowledge: Inspection of a user's credential can prove the holder's entitlement to the credential without revealing any persistent information.*

Active and Passive Models

For all the information exchange in trust establishment for federated networks, participating entities in that interconnected environment may be either passive or active. Passive entities wait to be contacted by active entities, while active entities are capable of initiating interactions or communications with passive entities or active entities. The distinction between active entities and passive entities allows for flexible deployment of entities for trust related activities over multiple security domains, such that some entities may only actively interact with a trusted set of partners, while others may passively listen for one or more interactions or service requests from strangers. With these different types of entities, several privacy control models are possible.

- Active model: From the point of view of active entities, the requirements of privacy control can be 'pushed' or 'advertised' first, and then potential partners can follow corresponding policies for subsequent trust related activities.

- Passive model: From the point of view of passive entities, private information and attributes are always kept as secrets; privacy control is applied to those kinds of information when that information has to be disclosed or released.
- *Hybrid model: Active and passive entities keep their roles while they work together to provide privacy enhancement in the interactions for trusted related activities.*

We will apply a hybrid model that takes advantage of both active entities and passive entities to enhance privacy protection for trust establishment using web service enhancements. Flexible but effective privacy protection is possible by designing and implementing a comprehensive framework that incorporates all these different models and facilities.

Privacy Protection in Indirect Trust Establishment

Owner control is embedded in our proposed bridging protocol for indirect trust establishment. Any participating parties can decide which subset of privileges granted by the common third party will be used as the foundation for new trust relationships. Anonymity and proof of knowledge are also achieved by subsets of privileges, because different subsets of privileges imply different levels of trustworthiness for different new relationships. In indirect trust establishment, A and B choose active model, and C (the common third party) chooses the passive model in order to keep A's and B's privileges as secrets until they are willing to disclose them as the foundations for new trust relationship. Privacy is also protected by using commonly granted privileges instead of private attributes to negotiate new relationship is the bridging protocol.

USING WEB SERVICE ENHANCEMENTS TO PROTECT PRIVACY FOR DIRECT TRUST ESTABLISHMENT

Since privacy protection is also a concern in direct trust establishment, which involves direct negotiation between participating parties, we propose another privacy protection mechanism for direct trust establishment. We introduce two new elements, trust primitive and trust group, to facilitate privacy protection in this process.

Trust Primitive and Owner Control

Definition 1: *A trust primitive is defined as the minimal subset of attributes in a pre-packaged digital credential, which has a complete semantic meaning according to a set of policy requirements. A trust primitive is signed by the credential holder, which is either an individual user or a security domain.*

In the proposed privacy protection of direct trust establishment for web service environments, a trust primitive is represented as a subset of attributes in the attribute service and conveyed as an XML element when it is exchanged between securities domains. As illustrated in figure 2, trust primitive 1 corresponds to an electronic library access rule with three required attributes (4, 6, and 7). The holder of the digital credential can form this trust primitive element and will be allowed to use the electronic library if the server can verify that its three attributes are valid (that is, if the token has been issued by an acceptable authority, the token is not expired, and the holder operates in the role of student, faculty or staff). Since neither the name nor ID number is part of the set of attributes associated with this trust primitive, anonymous access is permitted. Trust primitive 2 is for library checkout. It contains the same three attributes in trust primitive 1 plus attribute 2, ID number, which is needed for library accounting. Trust primitive 3, consisting of attributes 3, 6 and 7, might be used to verify same-sex gender before granting entrance to a dorm floor, or by substituting attributes 1 or 2 for attribute 3 it might be used to verify a specific individual's residence on the dorm floor before granting entrance.

A credential holder forms a trust primitive voluntarily. Every request of retrieving a trust primitive from an outside domain will be verified by the attribute service to selectively disclose the subset of attributes associated with the trust primitive. Another merit of trust primitives is that they prevent initiation of selective disclosure from anyone except the credential holder. Thus owner control is achieved. Figure 3 shows the workflow of the proposed protocol working with trust primitives for privacy protection in direct trust establishment.

In this protocol, a service requester and a service provider (two principals) from different security domains are assumed. Before the beginning of this privacy protection enhanced trust establishment workflow, the attributes of the service requester are stored at the attribute service of the service requester's security domain. The requester is also assumed to hold a security token containing its identity and other security related information. The workflow is initiated by a need for the requester to disclose some of its attributes to the service provider for negotiation.

Figure 2. Attributes and three possible trust primitives

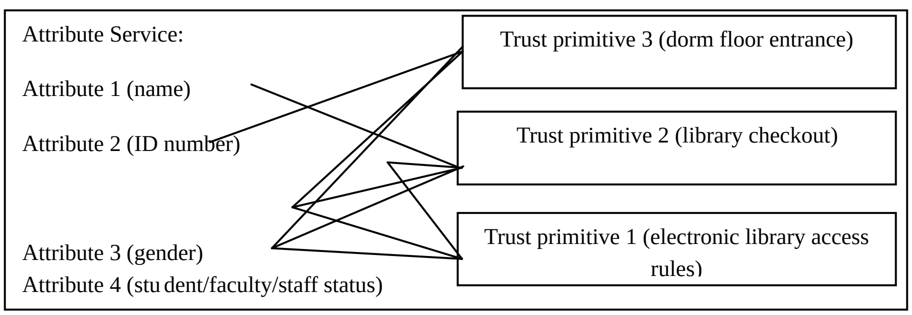


Figure 3. Workflow of privacy protection protocol for direct trust establishment

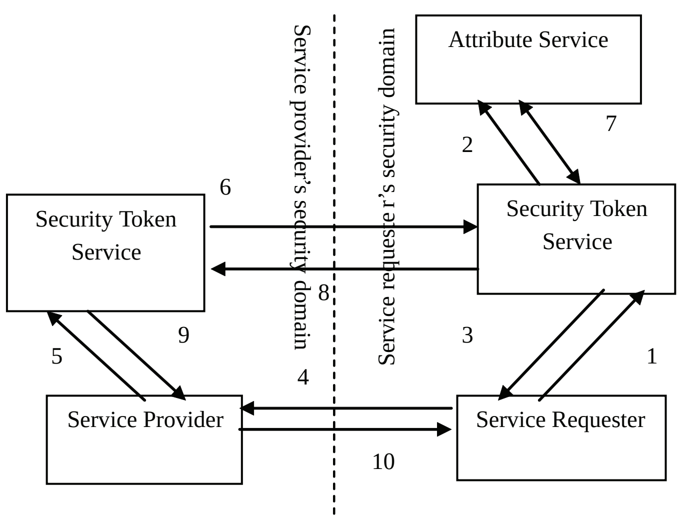

This need could be triggered by the access policy of the service provider's security domain, which is publicly accessible via a policy document, or by the service provider's direct request for the requester to provide one or more attributes. Thus a hybrid model is accommodated in this privacy protection protocol. Then the workflow executes from step one through step ten to finish a round of information exchange for trust establishment process. Step numbers below correspond to the numbered arrows in figure 3.

1. After reading the service provider's access policy or receiving a request for proving some attributes to obtain access, the requester initiates a service request, which contains the trust primitive corresponding to the policy or request for attributes from the service provider, to the STS in its own security domain. The security token held by the requester is also embedded in this service request message for proof of identity.
2. When the STS receives the service request, the STS extracts the security token from the message, verifies the legitimacy of the security token, and registers the trust primitive at the attribute service in its own security domain.
3. Then the STS adds this trust primitive to the requester's security token, re-signs the security token, and sends it back to the requester.
4. When the requester gets the newly signed security token, the requester embeds the security token in the access request and sends the request.
5. After receiving the requester's access request, the service provider asks its own STS to check whether the request complies with the service's access policy.
6. The STS of the service provider sends a request for attribute verification to the STS of the requester. The newly signed security token of the requester is sent together with the request.
7. The STS of the requester extracts the trust primitive, which corresponds to the access policy of the service provider, and uses this trust primitive as the query keyword to search the attributes disclosed by the requester at its attribute service.
8. The STS of the requester returns the attributes retrieved from the attribute service.
9. The STS of the service provider performs verification and sends its decision regarding the access request (granted/denied) to the service provider.
10. If access is granted, the service provider performs the requested operation and returns information to the requester; otherwise the provider issues a denial.

Sometimes the requester also needs to verify some of the service provider's attributes to negotiate a trust relationship, so the roles of the requester and the service provider can be interchanged. Several rounds of exchange form the negotiation needed to build a trust relationship between the two principals.

Trust Group and Partial Disclosure

Definition 2: *A trust group represents a group of partners who comply with the same set of policy requirements. The partners here are entities who have direct trust relationships with the policyholder.*

A trust group name is associated with a set of policy requirements. For example, if the service provider creates a set of policy requirements in the form of a WS-Policy file for negotiation of a trust relationship, the trust group name will be attached at the end of the file. Every partner complying with this set of policy requirements will use this trust group name to represent the corresponding trust relationship. A WS-Policy file containing a trust group looks like this.

```
<?xml version="1.0" encoding="utf-8" ?>
<policyDocument xmlns="http://schemas.microsoft.com/
    wse/2003/06/Policy">
<policies
xmlns:wssp=»http://schemas.xmlsoap.org/ws/2002/12/secext»
    xmlns:wsp=»http://schemas.xmlsoap.org/ws/2004/09/
    policy»>
<wsp:Policy wsu:Id=»trustlevelsec-token»>
<wssp:SecurityToken wsp:Usage=»wsp:Required»>
<wssp:TokenType>http://www.contoso.com/tokens/
    customXml#TrustLevelSecToken
</wssp:TokenType>
<wssp:TokenIssuer>http://www.cs.virginia.edu/TrustLev-
    elSTS.ashx</wssp:TokenIssuer>
</wssp:SecurityToken>
<wssp:SecurityToken wsp:Usage=»wsp:Required»></
    wssp:SecurityToken>
</wsp:Policy>
</policies>
<trustGroup>TG001</trustGroup>
</policyDocument>
```

After negotiation, a new trust group element is added to the requester's security token, and the security token is signed by the requester's STS again. Alternatively, the security token is replaced by a new security token issued by the service provider's STS, which contains the corresponding trust group element representing the new trust relationship. A trust group element is represented by three XML tags (trust group name and two domain/individual identities). Every policy holder also needs to record all the trust group elements that the holder is involved, and so do the partners. The trust group element looks like this.

```
<trustGroup>
<trustGroupName>TG001</trustGroupName>
<domain1>http://abc.com/localSTS.asmx</domain1>
<domain2>http://def.com/localSTS.asmx</domain2>
</trustGroup>
```

Access requests after the negotiation are granted by a verification of the trust group element in security tokens. If the access requirement for a trust group element changes in a service provider's policy, then the service provider needs to revalidate the previous trust relationship by invalidating the old trust group element, asking for the requester's trust primitives again, and then verifying whether the new trust primitives meet the requirements of the changed policy. If access is granted, a new trust group element will replace the old one for future use.

PROTOTYPE SYSTEM

Implementation of Indirect Trust Establishment with Privacy Protection

We have implemented the whole trust establishment system using the Microsoft .Net platform. The .Net framework together with the Web Service Enhancement (WSE) 2.0 SDK (Microsoft, 2006), which supports the WS-Security (Nadalin, 2004) and WS-Trust standard (Anderson, 2004), provides a complete platform for our system implementation. All the building blocks in our system architecture use web services as internal interfaces. Figure 4 illustrates the system architecture for indirect trust establishment with privacy protection. With the help of the proposed bridging protocol, trust domains can establish new trust relationships by extending current trust boundaries more smoothly and more securely. In this system architecture, the STSs are the main portals for interactions across trust domains. The STS is in charge of issuing and exchanging security tokens, which contain critical information such as identities, privileges and trust-related information. A policy repository is used to store and retrieve policy requirements and the corresponding privilege information used by the bridging protocol. The negotiation engine controls the whole process of information exchange and negotiation step by step. Each trust domain has an entire deployment of this system. But according to the bridging protocol and indirect trust establishment process, the functionalities used by participants A, B and the common third party C are different.

In indirect trust establishment mechanism, we use the trust group element to represent an

established trust relationship. In a security token, the trust group element contains a name for the relationship together with information from the two domains between which the trust relationship is established. In the policy repository, every trust group element is associated with a set of privileges granted by another party. Figure 5 illustrates the different formats of a trust group element in a security token and in the policy repository.

Implementation of Privacy Protection for Direct Trust Establishment

Meanwhile, this privacy protection enhanced trust establishment system is a subsystem of a federated cyber trust system (Weaver, Dwyer, Snyder, Van Dyke, Hu, Chen, & Mulholland, 2003). It provides the functionality of negotiating, building, and managing trust for a web service environment. When the federated cyber trust system is applied to a healthcare environment with hospital, pharmacy, insurance and billing security domains, the shaded boxes shown in Figure 6 are the modules involved in the trust establishment system. Boxes with dashed border lines represent different security domains; boxes with solid border lines represent modules in the hospital domain; arrows represent information flows or interactions. All the modules use web services as interfaces for their interactions.

We also have a graphic user interface to assist users to define and sign their trust primitives for privacy protection, which is shown in Figure 7.

Another concern is token formats. Among all the interactions between modules, there are two different types of interactions. One is the interaction between modules within a security domain. The other is the interaction between security domains. Two types of security tokens are used with different purposes to convey identities, credentials, trust group elements and other trust related information between service modules. We use username tokens to facilitate the interactions between service modules within the same security domain since it has little overhead and is easy to extend; we use SAML (Cantor, 2005) tokens to enable interactions between security domains since SAML is a recognized standard for interoperability among different platforms. Figure 8 gives examples of two token formats before being embedding into SOAP messages.

The architecture of our privacy protection enhanced direct trust establishment is illustrated

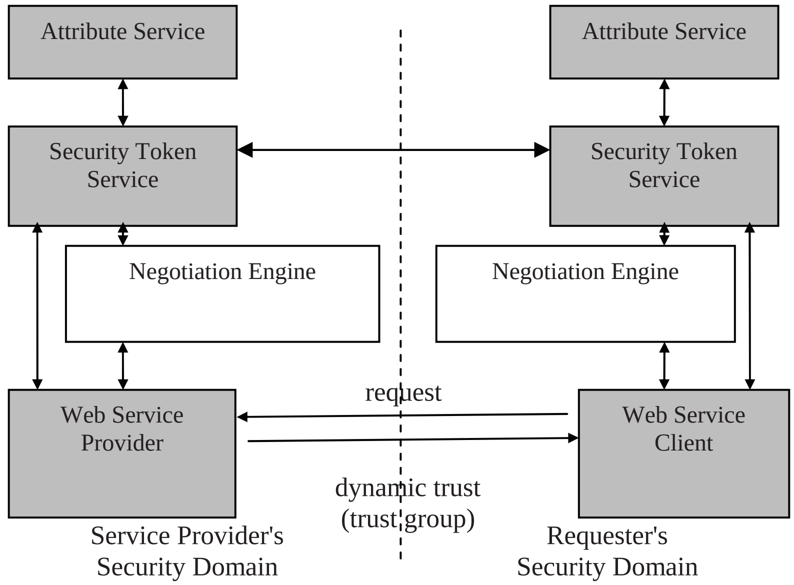
in figure 9. The web service requester and web service provider build a dynamic trust relationship via negotiation engines and security token services in both security domains. The security token service in our implementation also includes a set of web services to interpret and exchange security tokens. At the same time, the security token service uses an attribute service to register trust primitives for the requester. Negotiation engines control the overall workflow to build trust relationships dynamically, which include the implementation of the protocol described in

Figure 9. The architecture of privacy protection enhanced direct trust establishment



the Using Web Service Enhancements To Protect Privacy For Direct Trust Establishment section for a single round of negotiation.

DISCUSSION

A Case Study for Healthcare Applications

As we know, paper-based operations are still dominant in healthcare industry, because trust relationships in healthcare applications are still based on paper contracts and certificates. And third-party-issued paper certificates can still lead to privacy leakage. With new legislations such as HIPAA and Sarbanes-Oxley, strict privacy protection is imposed on healthcare applications. We here describes a detailed case study to illustrate how the proposed mechanisms and architecture can be applied to real healthcare applications to establish trust relationships with privacy protection using web services. Figure 10 illustrates the real workflows to build a new trust relationship when a patient needs to fill a prescription at a new pharmacy using web services, and to bridge a trust relationship to another neighborhood pharmacy when the prescription cannot be filled at that pharmacy using existing between the neighborhood pharmacy and the hospital. First, a patient at the hospital tries to fill a prescription at a new pharmacy (pharmacy A). Then the direct trust establishment protocol is applied to allow the hospital domain verifying the required and the only required attributes such as pharmacy license from the new pharmacy to construct the new trust relationship for prescription filling. Then a part of the prescription cannot be filled by the new pharmacy. It forwards the partial prescription-filling request to a neighborhood pharmacy (pharmacy B). Assuming the neighborhood pharmacy has an existing trust relationship with the hospital, the two pharmacies can bridge a new trust relationship using the hospital as the anchor for partial prescription-filling request. Using our proposed direct and indirect trust establishment protocols can not only fulfill the required trust relationship constructions but also provide privacy protections in the trust relationship establishment processes.

Figure 10. A case study with interactions between a hospital and two pharmacies

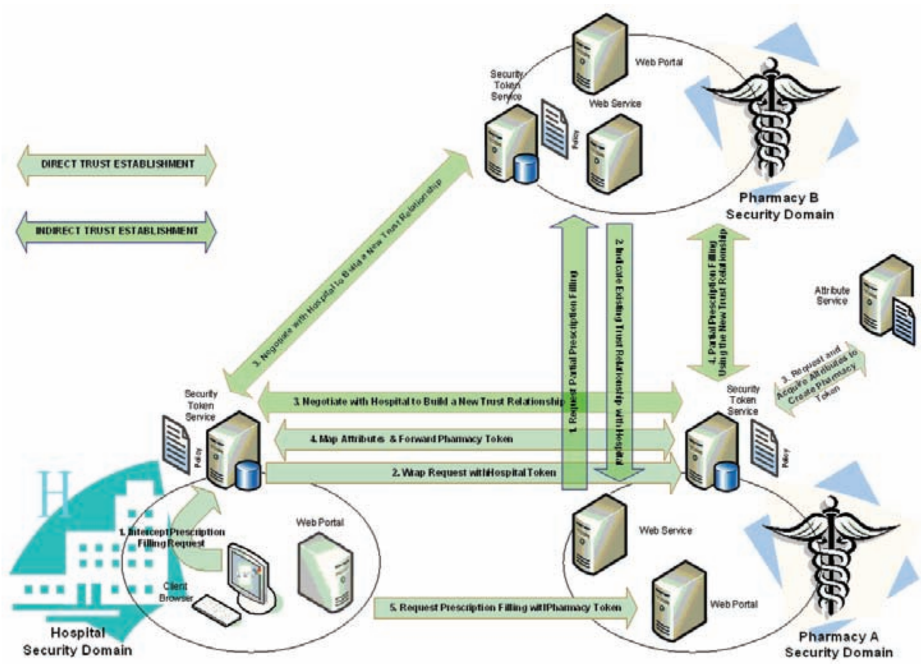


Figure 11. Comparison of direct trust establishment protocols' performance (with and without privacy enhancement)

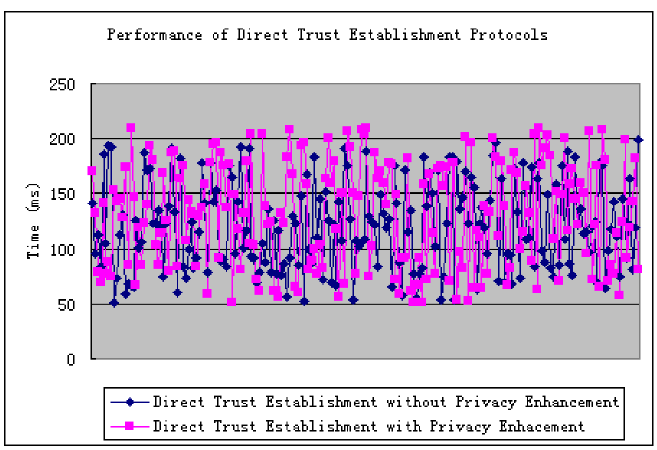

Performance Evaluation

For federated co-operations, management of trust needs to handle privacy protections within these co-operations. We achieve privacy protection for trust establishment via two protocols using web service enhancements. The proposed privacy protection mechanisms do not change the structure of other daily operations, such as user enrollment, user authentication, and verification. And the privacy-enhanced indirect trust establishment is achieved via a whole new protocol design using existing trust relationships, which avoids direct sensitive information exchanges. The privacy-enhanced direct trust establishment only enhances a few additional steps in federated co-operations using available features in WS-Policy, security tokens, and attribute services. These mechanisms can also be easily embedded into other trust establishment protocols with certain modifications.

We compared the performance of the direct trust establishment without privacy enhancement, which shows all the credentials available in attributes upon request, and the proposed privacy-enhanced trust establishment protocol described in the section Trust Primitive and Owner Control. We randomly choose trust establishment processes conducted by patients and hospital staff when new trust relationships need to be built with a new domain. We measured the time used for two trust establishment processes (see Figure 11). The blue (black) series is the direct trust establishment with privacy enhancement; the red (grey) series is without privacy enhancement. Although the difference of the time used for a single direct trust establishment process varies from 50ms to 198ms, the mean value of the direct trust establishment time with privacy enhancement is 128.08ms and the mean value of the direct trust establishment process without privacy enhancement is 123.51ms (a 3.70% difference). We found the overhead in performance is almost unnoticeable.

CONCLUSION

In this article we described an indirect trust establishment augmented with lightweight negotiation to achieve owner control and privacy protection simultaneously. Our research motivation comes from the inadequacy of binary trust and the difficulty of using subjective formulas combining multiple (even conflicting) trust values. Our new privacy protection mechanism in indirect trust establishment is an alternative method with these advantages:

- It introduces the negotiation process into the indirect trust establishment (bridging extant trust relationships), which assures that every participant has owner control over the decision-making process for new trust relationships.
- It prevents privacy leakage by exchanging privileges granted by the common third party instead of exchanging private attributes.

Also we described a privacy protection mechanism for direct trust establishment that extends the extant trust establishment mechanisms for web services to gain many advantages from its privacy control and dynamic capabilities. Our research motivation comes from the complicated privacy requirements inherent to current healthcare data management and similar sensitive information management. Our new trust establishment mechanism is dynamic with these advantages:

- It allows only the requester to choose what attributes may be viewed by the service provider. Therefore, it is capable of enforcing the requester's privacy.
- It allows only the chosen attributes to be viewed by the service provider. Therefore, it is capable of disclosing private attributes selectively.
- It allows any trust relationships to be renewed whenever the service provider's policy is updated. Therefore, it is inherently dynamic.

Our future research will focus on the topological impact of privacy protection mechanisms and their applications to privilege delegation and enforcement of trust relationships.

Chapter 8.13
The Interactive Computing of Web Knowledge Flow: From Web to Knowledge Web

Xiangfeng Luo
Shanghai University, P.R. China

Jie Yu
Shanghai University, P.R. China

ABSTRACT

Web Knowledge Flow provides a technique and theoretical support for the effective discovery of knowledge innovation, intelligent browsing, personalized recommendation, cooperative team work, and the semantic analysis of resources on Internet, which is a key issue of Web services and Knowledge Grid/Web(Zhuge, 2007; Zhuge, 2005). In this chapter, first the authors introduce some basic concepts related to Web Knowledge Flow. Next they illustrate the concepts of interactive computing, including the Web interaction model, the implementation of interactive computing and the generation of Web Knowledge Flow. Finally, the applications of Web Knowledge Flow will be given.

1. WEB KNOWLEDGE FLOW

1.1 Concept of Web Knowledge Flow

Many efforts have been done on the knowledge flow area. Some researchers study knowledge flow based on the organization of workflow, which is about the knowledge demand of the logic relationship and the role between the tasks of workflow. It can be realized by the way of pushing (Zhao, 2001; Wolverton, 1997). Taxonomy model aims at providing an overall picture of grid workflow verification and validation (Chen, 2007). Chen and Yang develop a novel checkpoint selection strategy that can adaptively select not only necessary but also sufficient checkpoints (Chen, 2007). Spiral model proposed by Nonaka describes the knowledge flow from epistemology to ontology. In the epistemology, knowledge flows from implicit knowledge to explicit knowledge, then from explicit knowledge to implicit knowledge. In the ontology, knowledge flows from person to group, and then from group to person (Nonaka, 1994; Nonaka, 1995). Based on Spiral model, Knowledge Flow Dynamic Model (*KFDM*) proposed by Nissen makes the knowledge flow over time explicitly. It can support a multi-dimensional representation that enables a new approach to analyze and visualize diverse knowledge flow patterns in enterprises (Nissen, 2002). Knowledge energy model proposed by Zhuge et al. takes knowledge energy as the driving cause to form an autonomous knowledge flow and explores the hidden principles (Zhuge,2005). The principles of knowledge flow engaged in cooperative cognition are explored by Dou from the perspective of learning and cognition evolution (Dou, 2006). Textual knowledge flow proposed by Luo et al. aims to provide an effective technique tool and theoretical support analysis for the discovery and cooperation of knowledge innovation, intelligent browsing, and personalized recommendation in Web services and e-Science Knowledge Grid (Zhuge, 2002). Other knowledge flow models are peer-to-peer team knowledge sharing and management based model (Luo, 2008), agent based model (Nissen, 2004), and the trust based model (Guo, 2005), etc.

Definition 1(Web Knowledge Flow, WKF):

Web Knowledge Flow(WKF) is a sequential link between topics with rich semantics, which is activated by user's demands and changes with the demands.

Compared with other multiple types of knowledge flow (Nissen, 2002; Zhuge, 2005), WKF has some special characteristics as follows.

- WKF reflects the flow of knowledge between topics on Internet;
- WKF contains rich semantics between topics, which leads to similar WKF, associated WKF, and causal WKF etc;
- WKF is activated by user's demands, in other words, WKF is a kind of service on demands;
- WKF changes with the change of user's demands.

When a user browses topics, a WKF is a browsing path of topics recommended to the user. When some browsing paths of topics are activated at the same time, one of them should be chosen and recommended according to user's demand.

As can be seen, Web knowledge flow provides a technique and theoretical support for the effective discovery of knowledge innovation, intelligent browsing, personalized recommendation, cooperative team work, and the semantic analysis of resources on Internet, which is a key issue of Web services and Knowledge Grid.

According to different relationship between nodes in Web Knowledge Flow, WKF can be classified into Association Web Knowledge Flow (Luo, 2008) and Similarity Web Knowledge Flow (Luo, 2008).

Definition 2:(Association Web Knowledge Flow, *AWKF*)

Associated knowledge flow is a sequential link with rich semantics between associated topics, which is activated by user's demands and changes with the demands.

Compared with other knowledge flows, *AWKF* has the following distinguished characteristics.

- *AWKF* can reflect the flow of knowledge between topics;
- *AWKF* can contain associated relation between topics;
- *AWKF* can be activated by users' demands, i.e., *AWKF* is a kind of service on-demand;
- *AWKF* can updates with users' demands.

When a certain user browses topics in the Web or an e-Science environment, *AWKF* is a browsing path of topics. When several browsing paths of topics are activated at the same time, they should be evaluated according to the user's demand and their contents, and then one of them should be chosen and recommended to the user.

Definition 3:(Similarity Web Knowledge Flow, *SWKF*)

Similar knowledge flow is a sequential link whose only difference from *AWKF* is that the relationship between topics in SKF is similarity relationship.

Therefore, if the user wants to browse similar topics on the Internet, an SWKF is helpful.

We know that web resources have two features in common:

- **Various Types of Representation:** Web resources exist in many kinds of representation: video, audio, text, and so on. First, it is impossible that the huge amounts of web resources are represented in one form. Second, different users have different requirement, which make the variety necessary. Even for one user, he/she must have different requirements in different time;
- **Out-of-order Organization Statement:** Web resources are distributed in out-of-order statement, which generates some challenges to the user's web activity, such as web search. First, out-of-order statement makes resource searching cost lots of time, which affects the search quality. Secondly, out-of-order statement can not lead to high accuracy of search.

On the other hand, requirement of users is not limited to one form of media. For example, the user may want to browse the web resources whose contents meet his requirement, whatever its representation form is.

Therefore, in order to facilitate high qualified web activity it is indispensable to do the following work:

- Unify the web resources into one representation;
- Organize all the web resources in order;

These are the basis for the generation of WKF. Element Fuzzy Cognitive Map(E-FCM) is used to represent web resource, whatever it is a video, audio, or text file. Semantic Link Network(SLN) is used to organize the web resources in order by introducing certain relationship. Next sections will include the contents of these two aspects.

1.2 Representation of Web Resource

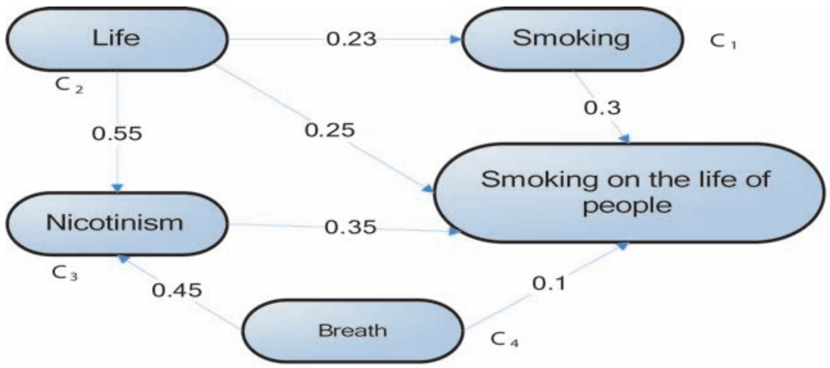
Element Fuzzy Cognitive Maps (E-FCMs) have a good capability to represent Web resource with rich semantics and can be understood by machine easily (Kardaras, 2006; Perusich, 2006). Therefore, E-FCM is proposed to represent Web resources.

Term 1:(Element Fuzzy Cognitive Map, E-FCM) Element Fuzzy Cognitive Map (E-FCM) is a fuzzy cognitive map, whose element concepts are represented by keywords; state values of element concepts are computed by the function of its frequency, position and font size in paragraphs or a section; theme concept is represented by the implied semantics of co-occurrence keywords appearing in a topic; the relations between concepts and their weights are represented by the relations between keywords and topic as well as their weights.

Figure 1 gives an example of E-FCM generated by the algorithm in (Luo, 2008), the vector of element concepts is {Smoking, Life, Nicotinism, Breath}

The knowledge of topic is represented by E-FCMs, which reflects the keywords' relations and their weights as well as the state values of co-occurrence keywords in a topic. Semantic information of co-occurrence keywords expressed by E-FCM is richer than a set of separate keywords

Figure 1. "Smoking on the life of people" represented by E-FCM (denoted as Topic 1)



because E-FCM stores topic information instead of the separate keywords of topic.

According to the capability of tagging topics, concepts can be classified into three categories (Luo, 2008): general concept, functional concept and seldom concept. Different type of concept has different contribution to the computing of web knowledge flow.

Term 2: (General Concept, *GC*) General concept is an element concept of E-FCM, which is a ubiquitous element concept appearing in an E-FCMs/topics library.

General concept has low capability of tagging topics for it has general semantics in an E-FCMs/ topics library. For example, in the domain of semantic Web, the keyword "semantic" has no specific function to tag topics because it is a ubiquitous concept in the topics library.

Term 3: (Functional Concept, *FC*) Functional concept is an element concept of E-FCM, which has specific semantics in an E-FCMs/ topics library.

Functional concept has high capability to tag topics for it has specific semantics in a domain. For example, in the domain of semantic Web, the keyword "OWL", "WSDL" have a specific function to tag topics because these keywords have particular meanings in the presented topics library.

Term 4: (Seldom Concept, *SC*) Seldom concept is an element concept of E-FCM, which has a low frequency in a domain E-FCMs /topics library.

Seldom concept has low capability to tag topics for it has a low frequency in a domain. For example, in the domain of semantic Web, the keyword "Knowledge Grid" has low frequency in the presented topics library.

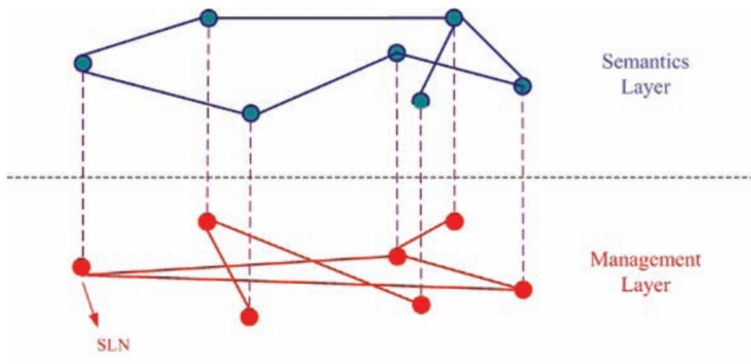
The semantic value of a seldom concept is bigger than a general concept. So when calculating semantic similarity degrees between topics, the common seldom concepts will bring bigger influences on the semantic similarity degrees than the common general concepts.

1.3 Ordered Organization of Web Resources

Semantic Link Network (SLN) (Zhuge, 2007) can link not only textual topics but also multimedia topics (e.g. relation of topics between text and video). Therefore SLN is introduced to link these Web resources based on the discovery of associated/similar topics, which can guide users' intelligent browsing of topics.

Term 5: (Semantic Link Network, *SLN*) A semantic link network consists of semantic nodes and semantic links (relations) between nodes. A semantic node can be a semantic community, a schema, a concept, a feature, an entity or an identity (Zhuge, 2007).

Figure 2. 2-layer Hierarchy Organization of Web Resources



The semantic link network (*SLN*) is designed to establish semantic relationships among various resources (data, image and various documents) aiming at extending the hyperlink network World Wide Web to a semantic-rich network (Zhuge, 2007).

Herein, the semantic nodes are the topics (e.g. multimedia topics or textual topics) and the semantic relations are the associated relations in a semantic link network. The knowledge flow based on *SLN* guides users to browse the cross media information[1] that makes the Web browsing more vivid, diversiform, and visual.

The web resources are organized in a 2-layer hierarchy way which is illustrated in Figure 2. The first layer is called semantics layer that the resources are organized by content and relationship with each other. The second layer is called management layer which is based on P2P structure (Dejan, 2002). Each node in these two layers is a SLN and represented by feature set. When a user's requirement is presented, first with semantics computing technique, the node which matches the requirement is located in semantics layer. Then mapping to management layer, the physical position this resource is got by P2P computing. Finally, similarity and association relationship computing is used to get the E-FCM which represents the specific topic and recommended to the user. After analyzing user's activities, analysis result is used in finding the node which has some relationship with user's preference. Then again, the node is mapped to management layer to get the physical position. In this way, a WKF is generated.

As can be seen, in this hierarchy structure semantics layer is used for high accuracy of web activity. Nodes on this layer are organized by semantics relationship which makes finding specific topic more accurately. Management layer is used for high efficiency of web activity. It has the special use of managing and locating resources. With P2P technique, the physical position can be got efficiently. In addition, by dividing all the web resources into several SLN, this hierarchy can deal with the great number of web resources well.

2. INTERACTIVE COMPUTING OF WEB KNOWLEDGE FLOW

When a user is browsing on the Internet, the topics he wants to read have some common characteristics in most cases. Maybe they all limited to one domain, or focus on one event. In other words, the topics have some relationship with each other. These topics that have the same relationship with each other are the nodes of WKF. How to find these topics according to a user's requirement is an important task. The key technique is interactive computing. It is a method which can get quantified information by analyzing user's requirement and behavior.

The key issues of generation of the WKF are the discovery of certain relations and the construction of the semantic links between topics. The discovery methods of association rules include Apriori (Agrawal, 1993), sequential pattern mining (Agrawal, 1995); episodes mining (Mannila, 1997); space association rules mining (Koperski, 1995); ring based association rules mining (Ozden, 1998); negative association rules mining (Savasere, 1998); association rules mining between affairs (Savasere, 1998); and calendar shopping basket analysis (Lu, 1998), etc. This section will introduce how to get the nodes of WKF and generate WKF by interactive computing.

2.1 Web Interaction Model

We know that Interaction Machine (Wegaer, 1997; Wegner, 1998; Goldin, 1998) is the extension of Turing Machine (Goldin, 1999).

Term 6: (Interaction Machines, IM) IMs extend TMs by adding dynamic input/output (read/write) actions that interact directly with an external environment (Wegner, 1998).

Interaction machines may have single or multiple input streams and synchronous or asynchronous communication, and can differ along many other dimensions, but all IMs are open systems that express dynamic external behavior beyond that computable by algorithms.

Term 7: (Interaction Histories): Observable behavior of IMs is specified by interaction histories.

As can be seen, the process of Web exploration can be modeled by interaction machine. The prediction of the user's next behavior is not only related to the user's present behavior and the history of his/her exploration. The behavior is represented by the semantics of the topic he/she browses. To describe the user's web activity and build the web knowledge flow, Web Interaction Model is given.

Definition 4: (Web Interaction Model, WIM) Web Interaction Model is used to build Web Knowledge Flow. It is a triad $M = (S, I, F)$, in which

--S is an enumerable set of states which describe the user's browsing state. Browsing state reflects the topics that the user have browsed and the interest that the user is interested in;

--I is an enumerable set of input states. Input state describes the user's behavior in browsing.

--$F : S \times I \to S \times O$ is a computable function which is called semantic computing of Web Knowledge Flow.

In WIM, the same input states may correspond to different output states, because of the history of browsing. With WIM, we can predict the user's interest and recommend corresponding pages to him/her.

The properties of WIM are as following:

- **Dynamic binding of inputs:** the input state may depend on the previous output. The user may react differently to different recommended topics which affect the input state;
- **Semantics dependence:** interactive computing is processing on the semantics layer of the organization of web resources. How to get the physical position of resources is the duty of management layer. In the process of computing, the semantics of topics are taken into account which makes the recommendation of topics based on content;
- **History dependence:** output can depend on previous history of browsing. The history of browsing is the basis for interactive computing;
- **Hidden information:** The user's interest is hidden and can be attained by semantics interactive computing with browsing history.

2.2 Implementation of Interactive Computing[2]

Semantics interactive computing is the key essential in WIM. It performs the task of semantics computing, and can be implemented by Markov Chain.

Assumption 1: Assuming that the process of user's browsing is in accord with homogeneous discrete Markov Chain. Therefore, the user's browsing process can be represented by a sequence which is composed of the web pages that he/she browsed.

This Markov Chain is represented by a triad $C=(X,P,\lambda)$, in which

- *X* is a discrete random variable. It is represented by an E-FCM which represents the topic user has browsed.
- *P* is the transition probability matrix. Each element p_{ij} of this matrix is the probability that topic_i transits to topic_j, i.e. after a user browses topic_i the probability that he/she browses topic_j.

$$P=\begin{vmatrix} p_{11} & p_{12} & p_{13} & \cdots & p_{1n} \\ p_{21} & p_{22} & p_{23} & \cdots & p_{2n} \\ & & \cdots & & \\ p_{n1} & p_{n2} & p_{n3} & \cdots & p_{nn} \end{vmatrix},$$

  n denotes the number of the total topics.
- λ is the initial state distribution of the topics. $\lambda=(p_1,p_2,\dots,p_n)$

In this Markov Chain, how to decide *P* is a key task. Before discussing the implementation of this model, some structures used here will be introduced.

Definition 5: History Vector, VH(t)

For each user, we use a vector $VH(t)=\left(h_1,h_2,\dots,h_n\right)$ to represent the history of his/her browsing history till the moment *t*. If the user browses the *ith* topic, then the corresponding element value v_i will be added by 1. The initial the value of *V* is $VH(t)=\left(0,0,\dots,0\right)$.

Definition 6: Visiting State Vector, (VS) Visiting State Vector $VS=\left(vs_1,vs_2,\dots,vs_n\right)$ is a vector which labels the topics that has been visited. If topic_i have been visited, then the vs_i should be set 1.

Definition 7: User State Vector, US(t) User state vector $US(t)=(us_1,us_2,\dots,us_n)$ is a vector which indicates the user's state which is related to the content of the topics that he/she browses. When a user browses topic_i, the topics which are similar to topic_i may also be interests for the user. Therefore, the user state *US(t)* should be computed by the following formula:

$$us_i=\frac{\sum_{j=1}^{n} v_j\cdot sdm_{ij}}{\sqrt{\sum_{j=1}^{n} v_j^2}\cdot\sqrt{\sum_{j=1}^{n} sdm_{ij}^2}}$$

On the other hand, the next topic the user may browse is related to not only other users' browsing history, but also the semantic relationship. The topic that has association relationship with this topic might be the one the user wants to browse next time. Therefore, the association relationship between topics should be taken into account.

$$P=\alpha\cdot ADM+\beta\cdot S$$

$$s_{ij}=\frac{a_{ij}}{\sum_{j=1}^{n} a_{ij}}$$

α and β are the weight of *ADM* and *S*, and $\alpha+\beta=1$. $A=(a)_{ij}$ denotes the number of visiting pair *i-j* in all the users' visiting history. Therefore, for each user, the user's state in the next moment *NS(t)* can be computed by the following formula:

$$NS(t)=US(t-1)\times A$$

If all the topics have not been visited, then the element which has the biggest value In *NS(t)* will be the topic that the user will probably interested in. Obviously, the user doesn't want to visit the topic that he/she has already visited again. In this paper, an AND operation is used to filter this kind of topics by the following formula:

$$NS(t)' = NS(t) \quad and \quad VS$$

Therefore, the biggest element in *NP(t)'* may correspond to the topic which will be the one that the user will be most interested in. And in the application, this topic can be recommended to the user.

As can be seen, in the process of semantics interactive computing, not only all the user visiting histories but also semantics relationship between topics are related to the state of topic. In other words, the content of the topics is taken into account in this paper which improves the accuracy of state description.

2.3 Generation of Web Knowledge Flow

Based on the discussion above, the main steps of construction of Web Knowledge Flow should be the following:

1. According to the user's requirement, generate its corresponding feature vector;
2. With similarity relationship, get the first node of WKF;
3. According to the user's behavior, update the history vector and visiting state vector.
4. With similarity SLN, attain the state of the user which is represented by *US(t)*;
5. With association SLN and the visiting history of all the users, attain the transition probability matrix *P*;
6. With visiting state *VS*, get the new *NS(t)'*, and take the element which has the biggest value as the next node in WKF, and update the visiting history vector by $h_i = h_i + 1$;
7. If all the value in *NS(t)'* are less than the threshold, then stop and the WKF is generated. Otherwise, go to 5).

In this way, the Web Knowledge Flow is generated. As can be seen that due to the semantics relationship including similarity and association relationship between topics are involved in the process of generation, the generated WKF can well reflect the user's interest and meet his/her requirement.

3. APPLICATIONS

In order to acquire many new customers and keep the existing ones, Internet-base business provides more objective information and better service. This section will show how to apply WKF to one important field, Web personalization.

With the help of user's browsing activities, interactive computing can be used to recommend some topics that the user may be interested to the user. For example, a user's browsing activities are traced, and some information are shown in table 1.

Then the corresponding history vector *HV(t)* is generated: $hv_{83}=hv_{79}=hv_{88}=hv_{228}=hv_{339}=hv_{443}=hv_{506}=hv_{542}=hv_{575}=hv_{704}=hv_{708}=hv_{913}=hv_{916}=hv_{925}=hv_{968}=1$; $\mathrm{hv}_{847}=\mathrm{hv}_{898}=2$.

We also generate the SLN with similarity relationship and SLN with association relationship of 1000 Web pages which belong to the field of environment. The corresponding SLN are shown in figure 3 and figure 4, respectively.

Then the corresponding WKF which is composed of five nodes(shown in figure 5) is generated. From the user's browsing history, we can see that the user interested in the topics about climate change. And the nodes of generated WKF are also focus on this topic. Therefore, WKF can well grasp the user's interest and recommend corresponding

Table 1. Records of Browsing Activity

Topic	Times of Browsing
Asia will bear brunt of climate change-linked deaths WHO	1
Aussies Kyoto should have been ratified	1
Australia, New Zealand to cooperate on climate change	1
Canada blasted by own environmental watchdog	1
Environmentalist pleads not guilty in OR	1
EU to adopt climate fight plan despite differences	1
FACTBOX What is the Kyoto Protocol	1
France's Besson plans film focusing on environment	1
Hewlett Foundation plans climate change grants	1
House bill lets California restrict car emissions	1
Nations seek compromise in climate change talks	1
Minorities the forgotten victims of climate change	2
Lawyers say considering court challenge to Korea	2

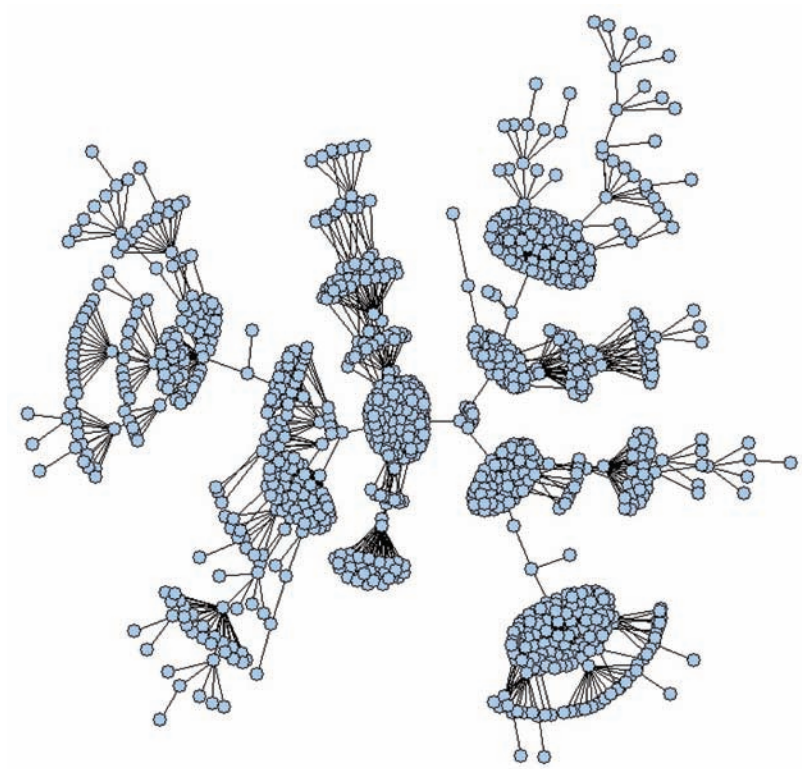

Figure 5. Generated WKF

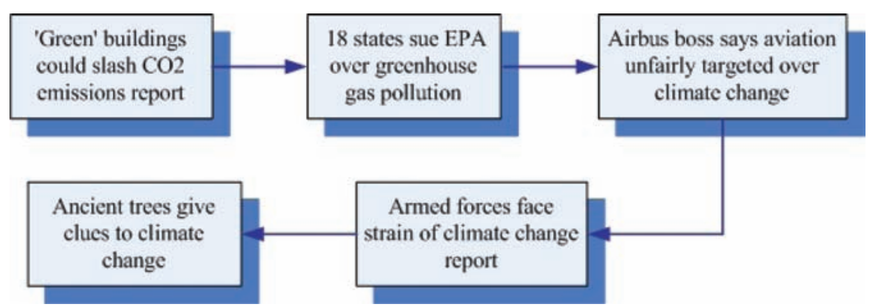

pages to him/her. In addition, it can be seen that the nodes in WKF are dispersed in SLN with similarity and SLN with association relationship. It accords with the dynamics features of WKF. With this generated WKF, the user can get his/her interested topics and doesn't need to search them by himself/herself on the Internet.

Chapter 8.14
Knowledge Producing Megamachines:
The Biggest Web 2.0 Communities of the Future

Laszlo Z. Karvalics
University of Szeged, Hungary

ABSTRACT

In the present study, the authors point of departure is the control crisis of science whose resolution requires radical social innovation. The author then shows that the only possible way for achieving this is the partial fusion of certain portions of scientific activity with the system of public education, by means of organizing scientists, teachers, as well as middle and high-school students into hybrid, knowledge producing mega-machines. The author shall subsequently argue that doing so will at the same time bring about a pragmatic shift in public education, for which professionals in the field of pedagogy have long been ready in principle and in theory. As a final result we shall see the emergence of science and public instruction tailored to the global system level, within the framework of the information society.

INTRODUCTION

The best way to predict the future is to invent it.
(Alan Kay)

The two perhaps most important sub-systems of the Information Society, Science and Public Education, are confronting a social innovation process of staggering force. Even though the research workshops of particular countries produce sensational results day by day, and the national systems of public education undergo continuing renewal, nonetheless in terms of their interest structures, their institutional mechanisms, and their financing, both science and public education have up to the present day continued to carry the imprint of the industrial era. For that reason, their functional disturbances can be managed ever less effectively by short lived pseudo-reforms of purely transitional impact.

The information technology background systems of modern sciences produce an incredible quantity of output signals. For many of the sciences (primarily genetics, oceanography, meteorology/climatology, environmental sciences, nuclear physics, pharmacology, archeology, and, first of all, astronomy) it is more and more problematic to manage the content of their permanently swelling background stores Beside financial resources the "human agent", human infrastructure, is becoming one of the bottlenecks. If we need brains in a "pre-digestive" process, it can easily find them where the task is exactly to make these brains able to do (even) scientific work: in the school benches. With the pupils socialized in the adequate community scope, involving resources and learning basic knowledge to satisfy their sateless desire to know and with their teachers an alliance may be created, and the biggest human GRID (the biggest Web 2.0. community) will be composed from these hybrid online clusters – the new type of knowledge producing and learning communities.

This process will, however, not run its course automatically. It requires efforts aligned with the same orientation, over several decades, by scientists from the various specialized fields, coordinators of instruction, political decision makers, teachers, social researchers, and information technological system developers. The final result guided by a vision, and the broad sweep of the project that builds the path leading to that goal, make for social innovation of a scope and importance whose like has never before been formulated either by the sociology of science, by the philosophy of education, or by research in futurology.

At this point our assertions concerning the future are hypotheses. Our aim is to elaborate scenarios ripened in a series of debates and work toward consensus-based conceptual structures, all of which will make it possible to initiate effective and soundly based social action and coordination, if and when the vision gains acceptence.

THE CONTROL CRISIS OF SCIENCE AND THE INEVITABLE CONTROL REVOLUTION

In the relevant literature there is a general acceptance of statements such as that the globalization of science has accelerated, that modes of knowledge production are emerging which follow new patterns, or that the rapid build-out of the new cyber-infrastructure of science introduces radical changes in methodologies of numerous scientific fields. There is, however, a considerable divergence of opinions concerning the depth of the challenge facing science and what the most comprehensive framework might be for interpreting the respective changes.

Beniger

On my part, I consider the model introduced by James Beniger in his epochal work, The Control Revolution (Beniger, 1986), to be the most fertile theoretical approximation. I hold so because the current situation of science can be elegantly interpreted using Beniger's category of a control crisis while also convincingly revealing the defining features of the incubating control revolution.

Shortly after the publication of his book, Beniger himself attempted to summarize in an independent study how his model might be extended to global science (Beniger, 1988).

The control revolution was the successful answer given to the lightning-fast process of industrialization which evolved during the century following the 1830's. Beside reining in speed and energy, adequate answers were successfully found to governance and enterprise management through technological innovations supporting the flow and elaboration of information, together with the social innovation of modern bureaucracy. Beniger's attention is drawn early to the double role in this process played by telematics, the increasingly interwoven world of information and communication systems. With its innovations, telematics supports the broad establishment of new and effective control structures. Yet in so far as the very processes whereby information is interpreted and evaluated for control purposes, are not successfully subjected to regulation over and over again by use of adequate methods, the feedback weakens and the system runs into new forms of control crisis.

When Beniger applies this to science, as a system constructed par excellence from the streaming of information flows, he perceives almost everywhere the indications of a growing control crisis. He finds the primary threat in the large-scale startup of new systems of telematics which disturb, or with their excessive radicalism—because they abandon a paper-based world—even disorganize, the accustomed flow patterns of already produced knowledge. Thereby they further weaken the functioning of the most important feedback mechanism, the citation system.

It is strange how completely Beniger (1988:26) is mistaken when he has fears for scientific reports, the publishing of specialized journals, or the publication of conference proceedings in their capacity as feedback mechanisms, on account of their exposure to information challenges. *"Telematics threatens global science … [with] … a crisis of control. Many involved with the computerization of information systems have predicted—some gleefully—a decline in the formal scientific paper, a blurring of the distinction between research notes and papers and between papers and the response to them by others, an increase in multiple authorship by scores or even hundreds who participate in a telematic discussion, and the decline of formal journals, editors, and the gatekeeping function more generally."* (Commenting on Beniger's work, Gerhard Fröhlich shares this anxiety (Fröchlich, 1996)

Surely, the last two short decades have brought a control revolution precisely from this point of view, with the creation of the new environment of digitalization, web-browsing, or full-text search capability. (For a summary of this point of view, see (Nentwich, 2005). And yet, at the same time Beniger's general model is more relevant than ever. The current control crisis of science cannot be found along the obstacles of accessibility to results; it has shifted to the scenes of new knowledge creation. By to-day the lack of feedback can already be attributed primarily and principally to system-level constraints on the interpretation of knowledge and of raw information and data.

Revolution in Sign Production, Shortage in Brains

Modern sciences, with their up-to-date information technology parks, are producing output data in quantities already so staggering as to make these incapable of being overviewed in a properly interpretive manner by the scientific community—which, to make things worse, is continually perfecting its capacity of producing and storing even more new information and data. *"New data – whole new types of data – are accumulating faster than researchers can make sense of them. The result is something like an optical illusion"* (Hugh Kieffer, cited by Norton, 2004). Those sciences which have high levels of demand for raw data and their interpretation—genetics, oceanography, meteorology/climatology, environmental sciences, atomic physics, pharmacology and above all astronomy—are currently undergoing the cyber-infrastructure revolution with their GRIDs, their enormous capacities for calculation, simulation and visualization, their more and more intelligent agents and work-flow devices.

Yet the scientists are aware of the control crisis. They all have the bitter experience that their efforts of building new models and coming up with pioneering connections and hypotheses are constrained by the small capacity of the analytic personnel available for handling lower-level, supportive transformational tasks. These tasks include surveys of measurement data, of elementary objects, or of relevant singular events; the testing of map structures; or the confirmation/ verification of masses of elementary correlations. Any successes achieved in automating or computerizing the analysis of the raw data will only reproduce at the next higher analytic level the experience of support personnel being unable to cope with the mass of transformational tasks.

In the past, scientists had met this experience only when surveying the specialized literature and running into the limits of the library services or the reference/abstract/search systems. Yet by now the capacity limit shows up in relation to the output of each scientist's own data—a control crisis that cannot be managed by traditional approaches. This is because until now the preferred tool of control revolutions was the automation/computerization of the kind of human intellectual effort that could be translated into appropriate algorithms, just as the computer itself had replaced human computations done by pencil and paper. (Grier, 2005)

Wherever this algorithmic translation can be continued—as in the case of robot librarians or the "robot scientist" used in gene sequencing—the impact of the control crisis can be moderated. As A. M. Weinberg says, *"extreme automation may be appropriate for those activities that are time constrained, it may lead to clogged information channels for those scientific activities for which time is less important than depth of understanding."* (Weinberg, 1989). Thus the scientific community has come step by step to the recognition that the bottleneck is in the areas of knowledge and insight that cannot be reduced to algorithms; the process of knowledge production is constrained by human brains capable of interpreting, placing in context, and thereby counterbalancing the sheer mass of raw data being generated. Therefore the new scientific control revolution can only arise from the human infrastructure, it can only be a human revolution—and as such calls not for technological but for social innovation.

PRELUDE TO THE KNOWLEDGE PRODUCING MEGA-MACHINES

During the past three decades the science establishment has tried to ease the intensifying pressure with three parallel minor innovations:

1. Organizational and institutional solutions facilitating the optimal use of the available capacities and numbers of human brains (*intensification*).
2. Interconnection of existing research staffs into virtual communities of ever growing size (*concentration*).
3. Attempted massive mobilization of new brains capable of being involved in the solution of scientific problems (*extensive growth*).

Each of these solutions yielded some temporary and partial results—but these results paradoxically ended up by reinforcing the basic problem, because of the increased demand for data production stimulated precisely by the successful feedback. We shall show below, one by one, why neither of the three approaches can be expected to promise further advance. Yet each of these three attempts has made a significant contribution to identifying the feasible path toward the real control revolution.

Intensification has time as its equivalent. When the staff of research assistants suddenly increases, this also means that we have to discover a way of reassigning the precious time of leading scientists to activities that yield higher added value. Sophisticated bibliographic software is meant to serve the same objective. And scientists gather into problem-centered invisible colleges which are arising in parallel with the hierarchies of traditional authority, in order to make sure that the time required to arrive at new insights will be shortened by means of an intensive exchange of knowledge. The fundamental constraint on such ways of intensification arises from the ever smaller part of the aggregate knowledge in a given area of science that has come to be represented as the personal knowledge of any one individual. As formulated close to forty years ago by an outstanding Hungarian economist, Ferenc Jánossy, "*Precisely this is why we have to beware of tugging by sheer force at the net of individual knowledge, trying to cover all of the increased area, until the meshes are torn and only large holes remain instead of the dense coverage of the net.*" (Jánossy, 1975). This recognition opens the way to the search for more decentralized and democratic knowledge production models.

Concentration is embodied in ever larger cooperating communities of researchers. The pioneering Human Genome Project has been followed by several similar research undertakings whose common element is the allocation of human resources required by such extensive research tasks, on the basis of novel principles.

Precursors

At the end of 2006 more than 100 thousand scientists from more than 175 countries have taken part in the **Innocentive initiative.** The website (http://www.innocentive.com) organizes the cooperation of world-level researchers as *problem solvers*, and companies wishing to solve their development questions focusing on science, as *seekers*. It is effective primarily in the search for innovative answers given to complex challenges, mainly in the fields of pharmacology, biotechnology, chemistry, food industry and plastics industry, with financial awards often exceeding $ 100,000.

The **Academici** website offers a search framework constructed for facilitating any emerging scientific cooperative initiatives and has thereby made it possible for scientists and researchers anywhere in the world to share their experiences at any time without limits and restrictions or to discuss any questions, proposals, suggestions, or problems. On www.academici.com those interested can search according to several criteria, such as research field or scientific interest. In this way educational or scientific institutions located at the greatest world distances from each other can mutually get in touch in a matter of minutes.

The **DILIGENT project** of the European Union develops safe, coordinated, dynamic and cost effective test beds for virtual scientific communities, to facilitate the sharing of knowledge and cooperation. Involving the website (http://www.diligentproject.org/), experiments are proceeding in two real-time application fields, an environmental sustainability project and a cultural-heritage preservation topic, by combining the Grid and the DL (digital library) technologies. It is readily apparent that from the point of view of control structures, the size constraint is given by the maximal number of the scientists who can be meaningfully interconnected. Meanwhile, the cooperative forms, workflow solutions, software systems, and online cooperative cultures created for several tens of thousands of participants are already paving the way for making possible the operations and organization of research communities of several-million-members which are expected to emerge in the course of the control revolution.

The Advent of Participatory Citizen Science

Extensive growth comes from drawing into science some social groups that had earlier, to some extent consciously, been excluded. The orientations of citizen science and participatory research (Irwin, 1995, Park et al., 1993) do not fight for the renaissance of amateur science but for the integration of knowledge created outside the scientific establishment, into the scientific problem solving processes. Typical examples, often with the spirit of movements, come into being and evolve in order to support the scientific emancipation of indigenous knowledge, that is, knowledge concerning the local environment, weather, therapies, animals or plants.

There exists, however an even more comprehensive context, the aspect of "open science" which fights, on theoretical and historical grounds, for breaking down the walls between Science and Non-science (Dasgupta and David, 1994). Open science, in the spirit of a new ethos (actually, one harking back to the 17th century) and fired by powerful economic arguments, carries the banner for a program of broadly spreading out such knowledge as already exists, and hopes from this — among other things — for a growth in the number of persons involving themselves in the cultivation of science. The attraction of new brains has been started in several ways, based not upon theoretical but rather very practical considerations, by drawing participants primarily into problems of the environment and sustainability, because of their personal exposure and ready competency. The projects with the broadest participation are, however, connected to space research where millions of amateur astronomers have even earlier been able to get into the scientific establishment with their observations and results. In the highly computation-intensive SETI@home project only the redundant computer time was lent by more than four million people, but in the Stardust@home project voluntary brains were already also being needed, in order to act as virtual microscopes in the identification of collected micro-particles. (The *Johnson Space Center,* with the help of the *Planetary Society* and the *University of California at Berkeley,* has performed a high-resolution scan of the so called aerogel used for capturing spatial dust. The scanned micro-images are available in 700,000 movie-length segments via the Internet, containing less than 50 expected micro-particles scattered like needles in a vast haystack. Results obtained in interpreting the images by voluntary scientific participants joining in from the public, if proven reliable by tests, will help in finding and isolating individual micro-particles. These will be named by their discoverers (http://planetary.org/programs/projects/stardustathome/).
This monotonous and tiring work required what amounts almost to a hunt for volunteers, who were permitted to join the search after successfully passing a test.

Practices of bringing new brains into science, undertaken so far, clearly demonstrate that in selected cases this may lead to success; it does, however, not provide a system-level solution to the problem of the missing human infrastructure. Voluntarism and contingency cannot be reconciled with a systemic revolution of control. And yet, we owe a lot to these projects, because they are proving day by day they that it is possible both to imagine and to operate problem solving communities of never seen size, and to boot, with outsiders. In the public discourse, they strengthen narratives relating to the decentralization, democratization and massive expansion of science, and thereby they open up the door to the real control revolution—the creation of knowledge producing mega-machines.

PLAN OF A MEGA-MACHINE

The mega-machine is Lewis Mumford's noted category (Mumford, 1967, 1970). Studies in the history of technology often refer to it as the term for a large and hierarchically organized task community—from the pyramid builders to the many armies of history. Mumford intended, however, to convey more than a simple metaphor. He was in part also interested in how the human components of a mechanism cooperate with the tool components, the mega-technics; how a few large cities which attain a central role in communications, labeled megalopolis, become the scenes of these events; how social control of technology emerges; and how communities of this size can be described with the terminology of cybernetics. Mumford (1967:191-192) was interested in how "*… to turn a random collection of human beings... into a mechanized group that could be manipulated at command. The secret of mechanical control was to have a single mind with a well-defined aim* *at the head of the organization, and a method of passing messages... (to) the smallest unit."*.

We can even consider the information society itself, in its most comprehensive sense, as a mega-machine (May, 2000). Yet we find the expression especially useful when we are looking for a name to designate the kind of knowledge-producing communities that will be able to exceed the largest present scales of scientific cooperation perhaps a hundredfold. And since we have seen the short-comings of current efforts aimed at increasing the number of brains participating in scientific research tasks, the conditions outlining the criteria that future scientific mega-machines will have to fulfill have become quite clear:

- Guarantee of staffs of sufficient size.
- Guarantee of staff availability.
- Professional-methodological quality assurance of activities.
- Accountability, dedicated areas of responsibility, deadlines met and capable of being met, clear project scenarios, and professional management.
- Organized transfer of or instruction in the knowledge minimally necessary to join a project.
- Facilitation of tasks, continuous mediation among individual participants of the system.
- Flexible, many-sided online system management service, oriented to facilitating horizontal as well as vertical interactions.

But where could the many tens of millions of brains be found for this? How could communities of this size be made manageable and operable in line with the above expectations?

According to a rough but conservative extrapolation based on UNESCO data for the year 2004 (http://gmr.uis.unesco.org/ViewTable.aspx), by 2007 there were approximately *800 million students* in the 12-18 age cohort, supervised in an orderly and structured manner by some *40 million teachers*. Public education is a human mega-machine that is already at hand, striving, to boot, toward a fully online existence at astonishing speed. It appears to be perfectly suitable, while radically renewing its current functioning, to become at the same time also a mega-machine for research, thereby solving the control crisis of science. Or put in a different way, other than the hundreds of millions who are now articulated into the national systems of public education, we can find no social group on earth or in heaven that would so completely satisfy our prior expectations concerning size, availability and organization.

Why is it then that this statement, when we first come upon it, should nevertheless feel so startling, bizarre, and utopian? Indeed, once we realize that it is necessary, we only have to convince ourselves that it is possible. If we accept the goal — to plan and put in motion the new mega-machines built on public education — then we can take our time pondering the details of the path that will lead us there. So the challenge does not lie in listing all the steps that are indispensable for implementing the initiative but rather, in figuring out how to make the vision itself realistic. Can it possibly be sustained as a hypothesis? Is a mega-machine conceptualized in this way at all imaginable? Is it outlandish in relation to the institutional and functional order of public education or to the contrary, is it wonderfully adaptable to that order? But above all, why do we find it so hard to throw ourselves enthusiastically into listing the fantastic functional consequences that we hope will flow from the birth of the new mega-machine?

Perhaps it sounds strange at first but it is impossible to find a single serious and objective counter-argument. Yet acceptance of the vision is all the more impeded by hardened views, mistakes, preconceptions, misunderstandings and optical illusions, which must be brought into the open, exhibited, and demolished before we can once again take a searching look at the vision itself. As it usually happens, when seeking to define the outlines of the Future, we run into the attitudinal roadblocks of the Past.

EDUCATION: THE SPIRIT OF THE INDUSTRIAL ERA, OR THE DELAYED CENTURY OF THE CHILD

Ellen Karolina Sofia Key wrote her emblematic book entitled The Century of the Child in 1900 (Key, 1900), a polemic discourse in which she attempted a showdown with the shadows of the 19^{th} Century. Ellen Key envisaged a radically new 20^{th} Century built on a positive child image, in which the schools would no longer deliberately freeze but rather set free the intellectual and spiritual energies hiding in the child. Sadly, the Swedish author was mistaken. Despite all the emancipatory, promising initiatives of that century, the real turnaround is still waiting in the wings. The school as an institution has shown an appalling lack of change ever since the end of the 19^{th} Century. Its objective function pursues social and labor market integration, its image of the child is paternalistic, and its pattern of knowledge flow is determinedly one-way. The school decants the necessary abilities, skills and knowledge into the child's head with the help of the teachers and the material of instruction, while keeping the child's time budget, comportment, and knowledge organization under strict control, standardizing the required minimal levels of knowledge. The reason why the tired commonplaces of the so-called world crisis of education never mature into an interpretation as a control crisis, is simply that the school is actually experiencing no crisis at all, it is fulfilling its task, the feedbacks are working — just so long as the fundamental assumptions and criteria of success continue to be those of the industrial era. Likewise, the science of the industrial era is not in crisis, either, because the processes of selection for the replacement of its cadre of scientists are continuing smoothly without any hitch. (And of course the alarm bells are immediately rung as soon as the process begins to falter somewhere, with particular disciplines attracting insufficient interest on the part of the relevant age groups.)

But let us now replace the out-of-date objective function with that of the information era. From the point of view of up-to-date knowledge asset management, is the school getting a suitable return from the brains committed to its care? Does it deal with the knowledge carried by the students on the basis of an appropriate valuation, does it regard such knowledge as a capital asset, does it make an effort to integrate that knowledge in a truly transformative fashion as much as possible with the total mass of knowledge?

If we measure the school's quality of functioning by how well it creates a foundation for the holistic image of the human essence as one of life-long learning, then it is immediately apparent that we are in deep trouble. The crucial question therefore becomes whether a totally and essentially industrial-era mega-machine might be capable of renewing itself by assimilation to the demands of the information age, or whether the imperative of change must necessarily aim at dismembering the mega-machine itself. Ivan Illich's answer was clear, definite and scandalizing: the school as an institution was itself the chief obstacle to renewal.

The current search for new educational funnels must be reversed into the search for their institutional inverse: educational webs which heighten the opportunity for each one to transform each moment of his living into one of learning, sharing, and caring. (Illich, 1970)

In my personal opinion, a process of creative destruction leads to far more difficulties than the re-planning and re-engineering of the mega-machine of public education. The school has changed much, to its advantage. For a long time, pedagogical theory has also been knocking on the door with a set of claims that it delineates normatively in connection with the school, the teaching/learning processes, and the children of the information age. Specifically:

- Education should move away from authoritarian orthodoxy toward a world of horizontal communications and of cooperating, problem solving teen-age student communities.
- Let us teach each child from an early age to think critically, thereby supporting the development of a facility that allows pondering problems from different perspectives and, even independently, with a thoroughness maturing toward the scientific level.
- The teacher should be an animator, not a device for the recitation of instruction material. The teacher should smartly direct the independent knowledge operations of the students that also make use of library and Internet resources, intervening only at critical points.
- Wherever possible, the principle of learning by doing and getting the children to make their own discoveries should replace mindless cramming.
- Education should build on children as self-confident and smart users of the world of information-technology devices and systems who are already on the brink of absorbing this experience and knowledge at the same time as their mother tongue.

If we want to build a pragmatic pedagogical program on the above theoretical expectations, we could nowhere find a better option than to involve teen-age students and their teachers by the millions into the suitably prepared and well-organized problem-solving processes, involving network communications and cooperative work, that are emerging in a number of scientific areas.

The spirit of the out-of-date industrial era is left with just one position it can take to save it from retreat. That is to call into question the suitability of the 12-18 age group for active and creative participation in scientific group work.

Mini-Einsteins versus Intellectual Immigrants

It may seem gratifying to collect a colorful posy of the latest acts of student geniuses. How a Hungarian high-school student living in Calgary, with two weeks' work, succeeded in proving Albrecht Dürer's five-hundred-year old geometric conjecture which had earlier resisted the mathematical community's best efforts? How a fifteen-year-old boy, jointly with his world famous co-author, published an excitingly original astrophysical hypothesis? How teen-age girls were involved in choosing the optimal landing point for the Mars terrain exploration robot?

Yet, what needs proof is not that talented teen-age students are at times capable of producing results comparable to those of grey-haired professors. We lose our way if we try to look for economy-size scientists among 12-18 year old children; the mega-machine demands something entirely different. The students, with the help of their teachers, must be capable of and suitable for appropriately undertaking massive partial tasks, typically of a low level of abstraction, yet still calling for natural intelligence. Let us replace one single research assistant with a hundred children and four teachers, and we will begin approaching realistic proportions. And ten thousand children with four hundred teachers may well provide us with as much problem-solving power for a scientific program as a research staff of one hundred. Of course, what we should expect from a student is, accordingly, one hundredth of what we may expect from an adult scientific researcher.

All this is well known by all those who had tried their hand at on-site scientific work jointly with massive groups of students. Where research programs, because of their very nature or a lack of support, have to make do without sufficient human resources, they increasingly turn to teenagers under the whip of necessity. Our space limitations preclude displaying the variety of color and the richness of form of currently running efforts of this kind. Tens of thousands of students are becoming articulated into research programs of great vitality, in the course of which they undertake full-valued ornithological observations, ecological surveys and measurements, or data collection efforts pertaining to local history. The exacting database of Estonian trees has been compiled by the student participants of the Tiger Leap program of the Estonian Schoolnet. The SG@Schools project in Singapore is being planned with reliance, in part, on the efforts of students in gene sequencing, animation tasks, and complex financial calculations.

The screenagers, representatives of today's generation that had grown up on television and the computer, are adapting to the new cognitive environment —according to Douglas Rushkoff's apt remark (Rushkoff, 1996),— as naturally and flexibly as the children of immigrants learn the language of the recipient country, faster and more effectively than their parents. And it is hard to imagine that the digital kids, who effortlessly cope with directing the traffic of the Chicago airport on a simulation game, who are daily managing extended online contact networks, and who can smartly transform information from one complex format into another, were not to be destined to accomplish even more. Would they not be suitable for administering questions in sociological surveys — perhaps concerning precisely their own age group? Or to read original sources and abstract their contents? Or to translate professional texts with their teachers' help? Or to answer questions, even by the thousand, put to them by scientists about what they find digging deep into their individually assigned little fields of inquiry? Or to try aggregating their partial bits of knowledge within flexible ad hoc communities? Of course they would. It would take no more than looking at them and seeing them in this particular way.

Still, many think that scientific activities are not for teenagers, that it is better to keep science at the level of illustrations meant just to awaken their interest, in order to make them disposed to learn. Their situation is therefore powerfully illuminated by the results of comparative educational surveys which show that if we integrate a broad collection of scientific problem solving methods, approaches, and philosophies into educational practice from an early age, we find an abrupt increase in children's disposition to learn as well as in their learning performance. Pedagogical action research has also shown that just as the acquisition of computer skills creates no particular problems, in the same way neither are there cultural, linguistic, religious or social obstacles to the acquisition of skills in undertaking activities of a scientific type. By transforming the public education system in a way that integrates information and science literacy into education from a very early age, we can promote an equality of opportunities more effectively than in any other way.

The children stand ready to become parts of the knowledge producing mega-machines. It is only the scientists, education-policy leaders, parents, and teachers who will have to come to believe this.

The Architecture of the Mega-Machine and its Impacts

In the coming years or decades, a series of research projects and experimental programs will put together and give precise shape to the basic structure and to the thousands of small details of the operation of knowledge producing mega-machines. In the discussion below I wish to survey, without any pretense to completeness, some of the fundamental aspects and characteristics that will almost certainly be relevant to the future system:

- Mega-machines will organize as hybrids of researchers, teachers and students which are multiply articulated in depth and in which assignments are distinguished as a function of the time requirement, profundity, and scope of each task.

- The age, experience, interests and earlier project involvements of each teen-age student will point to many differing roles. The representatives of science are also bound to arrive at specific divisions of labor amongst themselves. The ones facing, however, the largest shift in their identities are the teachers. At an earlier stage of their careers they had to choose between scientific work and the teaching profession which offers a lower social prestige. Yet as knowedge brokers, directors, and coordinators of bona fide research sub-projects, they will move into a totally new, inspiring professional and motivational environment, in their role as essential cogwheels in the functioning of the mega-machines. Beside this, the continuing role of exposition will also remain part of their responsibility — the awakening of interest, the nurturing of essential basic skills, and the incubation of the ability of students for participation in scientific group work.
- The disciplines currently experiencing the deepest control crises are the ones most likely to take the lead in building up their problem-solving clusters. These include genetics, biotechnology, and the environmental sciences as one set of fields; space research and astronomy as another; and finally, from among the social sciences, history and archeology.
- The inclusion of students in building project organizations can begin above the ages of ten or twelve. It seems to be obvious that there will be a particular system level that includes all students as parts of large, long-term undertakings aimed at structuring vast masses of raw information. This will involve the continuous follow-up of modular objects tailored to the capabilities of individuals (or of elementary research communities) and the steady enrichment of the knowledge pertaining to these objects (heavenly bodies, particular gene sequences, archaeological specimens, or historical sources), together with the mobilization, as required, of such knowledge. From here, not everyone's way necessarily leads to problem solutions at higher system levels, but all will remain members of this elementary problem community where one can continue doing one's modest partial task as long as attending school or even beyond, life-long.
- Within the mega-machine, dynamic cluster formation will necessarily get going along the typical attributes of the scientific problems under study. And since the unit topics, if they are well chosen, are likely to be multi-dimensional and complex, the students, in their capacity as individual owner/managers of particular dedicated problem objects, can be members of three, four, or even more problem communities organizing around particular attributes.
- The representatives of science are present in the system in part as clients who, on the basis of jointly agreed criteria, define the tasks to be undertaken. The tasks then tend to spread out within the mega-machine, possibly with benign, multiple overlaps. The scientists are also present within the problem field continuously and interactively, with responsibility for quality assurance, the creation of professional-methodological standards, and enforcement of the latter. The system harbors the possibility of competition and choice; the potential topics compete for resources, and individual clusters are relatively autonomous in choosing the focus of their activities. The results obtained thanks to the mega-machines will be the shared treasure of humankind.

- Other than maintaining the national language in scientific work, the force field guiding the operation of the mega-machine is basically a global one. The clusters are kept in motion by horizontal contacts among students of diverse nationalities, languages, cultures and religions, and through such an interconnectivity a new, global consciousness emerges in a meaningful way.
- This is closely connected with global problems that have so far called for consciousness raising in part as a challenge to education. The school of the future—in James Martin's words—will also be a civilization school, since it demands that the basic knowledge necessary for the survival of civilization be introduced into the curricula urgently and in their full range. "Education for survivability—the most important subject we can teach." (Martin, 2006). A work of similar outlook and message but with richer development of the topic is (Adams and Carfagna, 2006).
- Yet all this will be perceived as more organic and credible once everyone gets a share in laying a scientific foundation for the solution.
- For several reasons, the necessary lingua franca of the mega machine can only be English. (It is not impossible, though, that over the long run the torch will be taken over by an artificial language developed especially for this purpose.)
- Even though the research activities of the students are tied to practical reality by the objects of study individually assigned to them, the online work management systems nevertheless are taking on a key role in the process. It is an important question whether the open platform of the Internet is suitable for handling interactive efforts by several million participants, requiring work management systems of never seen dimensions. In any case, it is worth paying increased attention to software developments based on pioneering principles that promise solutions of entirely new levels of effectiveness. (We consider the Croquet project, www.opencroquet.org, as one of these.)
- Finally, it is important to emphasize that being a part of the scientific mega-machine will only be one side or one function of school life; there will be no total change of the guard compared to earlier solutions of instruction and subject matter, only an internal reorganization of proportions.

POLICY IMPLICATIONS

James Beniger notes correctly that in the case of large-scale social innovations it is always politics that has the decisive word: *" … the information society does not spring spontaneously from advanced industrialization. Technological possibilities for control present societal choices, which are themselves subject to political control"* (Beniger, 1988:22). And if innovation is global, as is the case with the future hybrid mega-machine of science and public education, then as an inevitable complication, two political system levels get in each other's way. Beside national education and science policies, the international organizations representing the global level are also very much concerned, since the mega-machine can only be coordinated in a transnational space. And although UNESCO's profile (science, education, infocommunication) would predestine the organization to lead such an important innovation program, looking at its current planning and operational system it is hard to imagine that it would be able to fulfill the task. It is more probable that the professional world organization of one of the scientific disciplines might come to a consensus about building a smaller pilot prototype of the mega-machine. And similarly, within the strategic-political decision space of the nation state it is hard to expect that a vision, no matter how realistic it may be, will gain priority, let alone support, solely on the basis of its projection of a future that is highly attractive in many ways. It is much more probable that the growing control crisis — whose spectacularly visible aspect is the increasing lack of financial and human resources compared with what would really be needed—will sooner or later inherently enforce the search for solutions. When national science policies see no other way, they will out of sheer necessity reach for the possibilities offered by the mega-machines.

It is especially difficult to realize and accept that in a global social innovation of such scope the expected benefits will not accrue in the form of traditional competitive advantages.

Why should the United States wish to turn in this direction, given that its leading position attained in science is sure to be safe for a long time to come, even without the upheaval of the mega-machines? When does the moment of epiphany arrive, insisting that the value of new knowledge produced by the mega-machine is becoming clearly measurable even under conventional budgetary criteria? How will the truth get to the point where it can be grasped—once again from a budgetary or national security perspective—that common actions organized in favor of common scientific aims reduce to insignificance or overwrite the traditional forms of international conflict? Let us not forget, it is part of the vision that the educational systems of the world's zones of conflict will also be integrated into the mega-machine. In the 21st century which offers little chance for religious, cultural or political convergence, could precisely science not become one kind of common language?

And what about the smaller countries? Is there any point for them to get going with their own mini-scale mega-machines? For example, on the basis of their recent educational and science-policy accomplishments, mentioned earlier, Finland, Estonia, and Singapore would without further ado be suitable and mature enough to experiment with sciences, themes, clusters—mobilizing in their entirety their teenage student cadres of hundreds of thousands. And what stands in the way of the possibility of these countries starting to build a mega-machine in cooperation with an ambitious country like Chile, with one of the Chinese or Indian provinces, or with one of the smaller American federal states?

Even the longest journey begins with the first step. Are we standing ready to initiate a discourse?

ACKNOWLEDGMENT

For the help I have received in preparing the final verson of this chapter, I wish to express my sincere thanks eminently to *Thomas Vietorisz* (Cornell University) and to *Adam Tolnay* (Stanford University), *Nicholas Vonortas* (George Washington University), *Gabor Agoston* (Georgetown University).

Chapter 8.15
Utilizing Past Web for Knowledge Discovery

Adam Jatowt
Kyoto University, Japan

Kyoto University, Japan

ABSTRACT

The Web is a useful data source for knowledge extraction, as it provides diverse content virtually on any possible topic. Hence, a lot of research has been recently done for improving mining in the Web. However, relatively little research has been done taking directly into account the temporal aspects of the Web. In this chapter, we analyze data stored in Web archives, which preserve content of the Web, and investigate the methodology required for successful knowledge discovery from this data. We call the collection of such Web archives past Web; a temporal structure composed of the past copies of Web pages. First, we discuss the character of the data and explain some concepts related to utilizing the past Web, such as data collection, analysis and processing. Next, we introduce examples of two applications, temporal summarization and a browser for the past Web.

DOI: 10.4018/978-1-59904-576-4.ch017

INTRODUCTION

As the Web changes continuously, it is necessary to preserve the past content of pages for a future reuse. The Internet Archive[1] is the best-known and largest public Web archive containing data crawled since 1996. Other Web archives exist, for example, ones containing Web pages from particular countries (e.g., Arvidson, Persson, & Mannerheim, 2000; Hallgrimsson & Bang, 2003). Besides, there are also numerous repositories of past copies of pages such as caches, site archives, personal page repositories or search engine caches.

Web archives provide a view on the history of the Web reflecting past societal states. Past content of pages can reveal the histories of underlying elements represented by these pages, such as institutions, companies, people or other entities. For example, one could approximately detect when a particular member left some laboratory by detecting the time point at which her or his name was removed from the list of laboratory's personnel. In general, the use of Web archives can greatly benefit researchers and practitioners in many areas, such as history, sociology or marketing.

Furthermore, analyzing information from the past can help not only in better understanding the history of our society but also understanding its present state. This is because Web archives can provide contextual information about Web pages and the objects or concepts discussed on them as well as their inter-relations. For example, we can analyze information from Web archives concerning a given company in order to use it as a context for better understanding the present information about this company. In general, mining past Web content has a potential to stimulate and improve the traditional Web mining process in the sense that it provides contextual information and sheds new light on present data.

Past Web is considered here as a part of the WWW space where pages no longer have any change potential; they are "frozen" past snapshots of pages. The live Web, on the other hand, is the present Web, containing pages that we can currently view online. These pages may be changed or updated and they usually provide full interaction capabilities.

In the past Web each page has its history and lifetime. Links between the old content of pages can be reactivated again. In this way, a temporal structure can be obtained reflecting connectivity between pages in the past. Another aspect of the past Web is missing data. A given content after its deletion from a page may never be reproduced if it has not been preserved in any repository. Besides, due to the rapid growth of the Web, selective type archiving often needs to be done.

In this chapter, we approach the problem of discovering knowledge from the past Web. First, we discuss the character of data that is used and methods for acquiring and processing it. We propose techniques for analyzing and selecting candidate Web pages for mining. This approach is based on analyzing long-term characteristics of pages with a special focus on their content changes as they are most interesting from the viewpoint of pages' evolution. Next, we introduce temporal summarization, which is an adaptation of a traditional text mining task into the past Web scenario. We propose summarizing histories of Web pages to generate abstraction of events and salient concepts described in selected portions of the past Web. We also discuss the possibility of discovering object histories in past content of Web documents. Finally, we describe an application for browsing and navigating the past Web. We show an implementation that is similar to those of traditional browsers for the live Web and of video players.

The rest of this chapter is organized as follows. In the next section, we discuss the related research and attempt to place this work in the wider context of text and Web mining. The following two sections describe the data accumulation, preparation and analysis. In the next section we discuss temporal summarization and investigate the possibility of object history detection from the past Web. The next section describes a browser for the past Web, while the last section concludes the chapter with a brief summary.

RELATED RESEARCH

Web Dynamics

The dynamics of the Web has been measured in many experiments (Brewington & Cybenko, 2000; Cho & Garcia-Molina, 2000; Fetterly, Manasse, Najork, & Wiener, 2003; Ntoulas, Cho, & Olston, 2004) which demonstrated that the content and link structure of the Web continuously change. Although many pages on the Web are short-lived, meaning they are deleted shortly after being created (Ntoulas et al., 2004), many important Web documents persist over time. Popular and main, or top-ranked, pages usually belong to this category as it often takes a long time for a page or site to gain popularity and accumulate a high number of in-links.

The results of Web dynamics research indicate the level of volatility of the Web as a whole. On the other hand, the study of update patterns of individual pages has been carried out for prediction of their future changes (Cho & Garcia-Molina, 2000, 2003; Ntoulas et al., 2004). The frequencies and degree of changes are the most often used measures to set up crawling schedules for maintaining fresh indexes of search engines. In practice, however, it is usually difficult to predict content changes in pages although some Web documents, for example, newswire sources, change in a more or less periodical fashion. In this research, we go beyond the simple analysis of change statistics as we focus on the distribution of content and its context over time.

Text Mining

Text mining is defined as a nontrivial extraction of implicit, previously unknown and potentially useful information from textual data. Text mining evolved from data mining and is a promising field as much information nowadays is stored in the form of electronic text. We consider our approach to be similar to temporal text mining, because, to a certain extent it resembles efforts that were taken in analyzing and mining streams of text data. Generally, mining news articles or other text streams along the time dimension has been studied well (Allan, Gupta, & Khandelwal, 2001; Allan, 2002; Kleinberg, 2003; Li, Wang, Li, & Ma, 2005; Mei & Zhai, 2005; Papka, 1999; Swan & Allan, 2000; Wang & McCallum, 2006). For example, the well-known TDT (Topic Detection and Tracking) research initiative (Allan, 2002) was aimed at detecting, classifying, and tracking events in news corpora. Recently, Wang and McCallum (2006) identified topics persisting over dynamic collections of documents. Another work showed the development of topic patterns in news articles over time (Mei & Zhai, 2005). Li et al. (2005) proposed a probabilistic model for retrospective event detection in news corpora. An approach toward temporal summarization of news events was proposed in Allan (2001) where novelty and usefulness of sentences retrieved from newswire streams were calculated for the construction of a final summary. Another related work called TimeMines (Swan & Allan, 2000) was proposed for finding and grouping significant features in historical document collections based on applying chi-square test.

While news articles and, in general, any text streams are usually represented as transient text snapshots, the content of pages often persists over time. Duration of content has certain relation to its semantics and relative importance in a page. Thus, in contrast to typical text data streams, one has to consider three types of content in pages at every time point: static (persisting over time), deleted, and added. Additionally, pages have certain inherent topics that determine the context of their transitory content and that can enhance the mining process.

Web Mining

Web mining is often described as the application of data mining techniques for extracting knowledge from the Web. It is traditionally divided into usage, structure and content mining. Web usage mining identifies the behavior patterns of users visiting Web pages for the purpose of optimizing Web sites. It is usually based on historical data, which is collected during certain time periods for its subsequent analysis (Cooley, Srivastava, & Mobasher, 1997; Kosala & Blockeel, 2000). Web usage mining can show how the users' access to Web sites changes over time. Web structure mining focuses on the link structure and graphical representation of the live Web. There have been, however, several approaches proposed to analyze the evolution of links over time (Amitay, Carmel, Herscovici, Lempel, & Soffer, 2004; Chi et al., 1998; Toyoda & Kitsuregawa, 2003). For example, temporal link analysis was used for detecting trends in page collections (Amitay et al., 2004) or for visualizing evolutions of Web communities (Chi et al., 1998; Toyoda & Kitsuregawa, 2003).

Web content mining uses the content of Web pages for knowledge extraction. Blog related research is probably the most prominent example of Web content mining in which the temporal aspect of pages is considered (Gruhl, Guha, Liben-Nowell, & Tompkins, 2004; Kumar, Novak, Raghavan, & Tomkins, 2003). Blogs help to detect and analyze social structures and social relations as well as provide information on society opinions, hot topics or recent trends. Blogs, however, are a unique media type as they usually contain complete versions of their past content with explicit timestamps provided as well as they are highly personalized and subjective. We believe that a general framework for mining any page types in the past Web is required.

Although most approaches to Web content mining generally neglected the temporal dimension of pages (Cooley et al., 1997; Kosala & Blockeel, 2000), there were, however, several works that investigated the usefulness of data on page histories for knowledge discovery (Arms et al., 2006; Aschenbrenner & Rauber, 2006; Jatowt & Tanaka, 2007; Rauber, Ascenbrenner, & Witvoet, 2002; Yamamoto, Tezuka, Jatowt, & Tanaka, 2007). Rauber et al. (2002) discussed the possibility of analyzing past Web data for identifying changes in Web-related technologies, particularly in the features and characteristics of Web pages, such as a file format, language, size, and so forth. The objective was to create statistics describing Web changes over time. Aschenbrenner and Rauber (2006) surveyed the work that has been done toward mining large portions of Web content with consideration of its temporal aspect. They also provided a general outlook on the potential of mining Web archives. Arms et al. (2006) have reported on building a research library for facilitating study of the Web evolution. This is an ongoing project aiming to build an infrastructure for analysis of massive portions of the data that is stored in Internet Archive. Practical usage of the past Web has been recently demonstrated by Yamamoto et al. (2007), who have proposed an application similar to question answering systems for extracting and combining knowledge from the Web and Web archives. It uses Web archive data for detecting changes in opinions and user knowledge over time.

Mining the content of the past Web is different from the usual Web content mining in several aspects. First, the temporal dimension of content and links in page histories poses new challenges and opportunities for understanding their roles and interrelations in contrast to traditional Web content mining. Second, pages and Web sites should be treated as dynamic objects having certain age, histories, trends, patterns, and so forth. Thus, the notions of a page and its content need to be separated in a way in which the latter one is considered as a transient component occurring in a higher level object, that is, a page. Content has then its own duration of occurrence while the page history is considered as the composition of different content occurring throughout the page's lifetime. Third, there is an issue of missing and incomplete data. In order to obtain satisfactory results, multiple snapshots of the past content of pages have to be found and acquired as well as approximation methods need to be applied for an optimal page history reconstruction.

DATA ACQUISITION AND PREPARATION

Data acquisition and preparation are important steps in the knowledge discovery process. In the mining of the past content of the Web these steps mean the retrieval of data from Web archives and the reconstruction of Web document histories (Jatowt & Tanaka, 2007). The following issues are involved here. First, it is by definition an ex post facto process, as the data is the past content of pages. If one could predict beforehand which Web pages are going to be used, one could simply set up a crawler with a suitable crawling frequency so that page evolution would be captured with a desired precision. However, it is assumed that the user is unable to make such a prediction, and rather that she or he wishes to acquire knowledge in real time using the available, preserved data. Hence, past snapshots of Web pages are gathered in real time from available resources with the aim of reconstructing the past with the highest possible precision. Thus, when talking about crawling in the context of the past Web, we mean querying past Web repositories for the data they contain. Second, because data is scattered in different repositories, it has to be searched for and identified before being used. Therefore, it is necessary to use efficient search and download techniques to locate and gather multiple snapshots of past content with a minimal cost. Due to the large size of data, in practice, usually, only its small portion can be fetched and analyzed locally. Therefore, the focus of this research is on the analysis of the limited amount of data rather than on building a framework for examining the past Web from a macroscopic viewpoint. In addition, there is an issue of the trustworthiness of past content, which is directly related to the trustworthiness of past Web repositories. For example, data obtained from a personal Web repository would normally be less trustworthy than the data collected from a large Web archive containing millions of pages and having a professional maintenance and control. Finally, only fragmentary data can be obtained due to the unpredictable change pattern of the Web and limited resources of archival systems. This calls for employment of efficient techniques for estimation of actual content that pages had in the past.

Collecting Snapshots

***Definition 1*:** Past page snapshot is a copy of page content that was published in the Web at a given time point in the past. The timestamp of the snapshot indicates the date when it was captured.

As mentioned above, because of resource limitations, Web archives contain only fragmentary past data. As a general attempt to alleviate this problem a kind of meta-archive approach (Jatowt, Kawai, Nakamura, Kidawara, & Tanaka, 2006) can be used to maximize past Web coverage and consequently to increase the precision of history reconstruction. This approach presumes communication with several past Web repositories at the same time. An intermediary module is required between these repositories and the local system to translate queries into the format required for each repository. After receiving a request for a page history, the module queries the repositories about their data. The repositories should then send a list of stored page snapshots with their metadata so that a fetching policy can be determined.

The optimal strategy would be first to check the signatures (checksums) of snapshots, if they are provided, in order to detect the ones that actually contain content changes from among all data provided by the cooperating repositories. This would prevent downloading identical page snapshots from different repositories, thereby maximizing fetching efficiency[2]. However, currently, Web archives do not provide such information. Instead, some repositories, such as the Internet Archive, provide lists of page snapshots that have any changed content when compared to the neighboring snapshots. By utilizing this information, only the snapshots with content changes inside archives would be fetched. In general, the efficiency of the data collection would depend on the metadata that is provided in past Web repositories.

Such a meta-archive approach would provide a unified interface to the history of the Web, making the data acquisition process less dependent on the resources of single Web archives. However, as Web archive interfaces are diverse, different data acquisition methods would have to be used. In addition, we make an assumption here that the URLs of pages remain the same over time, although, in practice, they may change even though the content of pages remains almost the same.

McCown and Nelson (2006) and McCown Smith, and Nelson (2006) have recently measured the persistence and availability of page copies inside the repositories of major search engines and the Internet Archive. The objective was to estimate the possibility and to provide methodology for reproducing the latest versions of Web sites in case of the loss of Web data.

Reconstruction of Page Histories

***Definition 2*:** Page history reconstruction is the process of reproducing the past content of a page using available snapshots for obtaining the continuous representation of page history.

***Definition 3*:** Optimal page history reconstruction is a reconstruction which accurately reproduces page history; that is, the errors resulting from such a reconstruction are equal to zero. Having determined an optimal page history, it is possible to recreate page content for any time point in the past that shows the actual content the page had at that time.

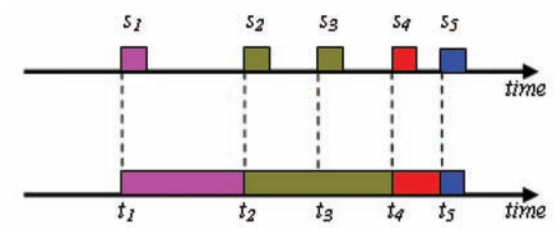
However, unless the page was unchanging, it has been crawled continuously or the implicit information about its past changes is provided, there will be usually some error involved in the history reconstruction. Only for certain types of pages, for example wikis, complete past data is available as the preservation of their versions is usually automatically done. In case of such pages, the reconstruction error would be equal to zero as all past changes can be derived from available page versions. In addition, some pages may contain temporal annotations in their present content that can be used to enhance the history reconstruction. For example, blogs often provide timestamps of content insertion. Nevertheless, for the majority of hypertexts, usually, neither implicit version management nor temporal annotations are provided.

We propose a simple approach for the page history reconstruction (Jatowt & Tanaka, 2007). First, collected snapshots are chronologically ordered according to their timestamps. If past snapshots are not associated with any temporal metadata then they cannot be directly included in the ordered sequence of past snapshots without a prior determination of their timestamps. For example, Yahoo! search engine provides cached snapshots of Web pages but it does not attach any timestamps to them. Estimating a timestamp of a snapshot could be possibly done by comparing similarities between its content and the content of other snapshots with known timestamps.

Second, every previous page snapshot is considered to represent the actual state of page content for the time period until the next page snapshot in the sequence. For example, suppose that five snapshots have been collected, s_1, s_2, s_3, s_4 and s_5, with timestamps, t_1, t_2, t_3, t_4 and t_5, where $t_1<t_2<t_3<t_4<t_5$ (Figure 1). Let us also suppose that snapshots s_2 and s_3 are exactly same. After the simple approximation, the page content is assumed to be the same as that in s_1 during the period $[t_1, t_2)$, the same as that in s_2 during $[t_2, t_4)$ and equal to s_4 in $[t_4, t_5)$. The reconstructed page history is then represented as a minimal sequence of 2-tuples containing different page versions and their starting dates ($\{(s_1, t_1), (s_2, t_2), (s_4, t_4)\}$ in the above case).

Page history reconstruction could be improved by considering additional information, for example, by analyzing changes in other pages belonging to the same site. Also, using the results of the temporal analysis of pages, especially their updating patterns, could make the reconstruction

Figure 1. Example of page history reconstruction



more accurate. Finally, historical snapshots of mirror pages, if there are any, could be utilized.

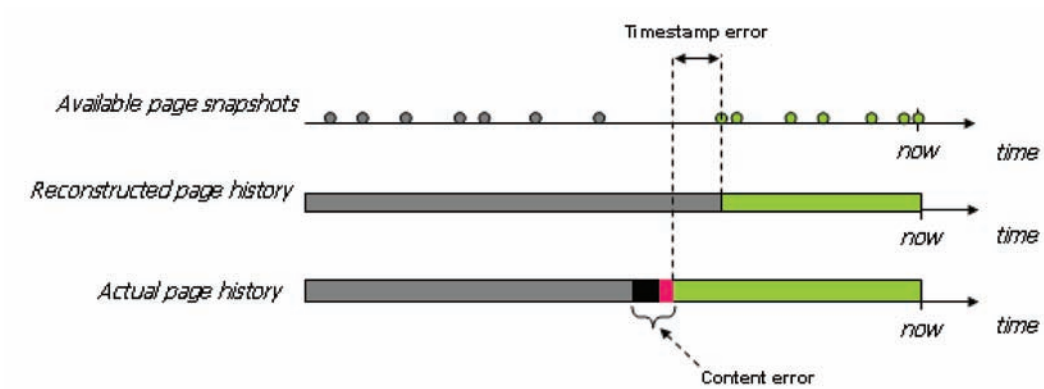
History Reconstruction Error

Usually, it is difficult to determine an accurate page history that would reflect the actual page content as it was at any arbitrary time point in the past unless the complete set of actual page versions is provided, for example, by a page author. Hence, mining the content of the past Web will typically be carried out using incomplete data with varying levels of precision and trust. It is thus necessary to consider the issue of missing data.

We can distinguish two types of errors in the page history reconstruction assuming that the page crawling was independent from the page update pattern (Jatowt & Tanaka, 2007). The first one, which we call a content error, is caused by uncertainty related to the content that appeared on a page in the past. Consider two retrieved past versions of the page (v_L and v_R) captured at time points t_L and t_R ($t_L<t_R$). The probability, $P(v_i)$, that there is any version v_i satisfying $t_L<t_i<t_R$ and containing any content different from that in v_L and v_R depends on many factors such as the length of the period from t_L to t_R, page type, content difference between v_L and v_R or the average change degree of the page. Intuitively, the shorter the time distance between the page snapshots and the more even their distribution over time are, the lower is the average probability of any transient, undetected content occurring in the page.

The second error type, which we call a timestamp error, is due to uncertainty in estimating the dates of content changes. The timestamp error, like the content one, depends also on the number of acquired past snapshots and their distribution over time. Figure 2 illustrates both error types. The top timeline shows available past snapshots of a page. For simplicity, let us assume that the page snapshots are empty (i.e., blank page) or they contain only one content element, be it a picture or a text snippet. Those snapshots that contain the element are marked by a green color, while the empty snapshots are marked by a grey color. After reconstructing the history of the page (the middle timeline) and comparing it with the bottom timeline that shows the actual page history,

Figure 2. Content and timestamp errors in the reconstructed page history



we can see that the reconstructed history contains both content and timestamp errors.

Site History Reconstruction

Pages usually belong to larger information units, or Web sites. Reconstructing histories of a Web site requires detecting the changes in site's topology over time and retrieving past content of pages that belonged to the site. As an input the starting page (e.g., the top page of a site), time frame *T*, and the depth *D* (i.e., the number of hops from the starting page) need to be specified.

The data accumulation system collects all available snapshots of the starting page that have timestamps within *T*. It then searches their content for any links to other pages on the site (i.e., pages having the same domain name). For each such a link, it collects available, previous snapshots of the linked page that have timestamps within *T*. These snapshots are then searched in the same way for links to other pages on the same site. The entire process is repeated until the specified depth *D*. In general, a page is considered to belong to the site's history if, during the time frame *T*, it was linked from another page belonging to the site at that time and if it was located a smaller number of hops from the starting page than the specified depth *D*. Intuitively, the number of page snapshots collected at the initial steps of the crawl (few hops from the starting page) has an influence on detecting pages at later steps. This is because pages may remain undiscovered if the links pointing to them occurred only in the undetected, transient content of other pages in the site. We call the error caused by the missing links a page error.

A site history is represented as a set of reconstructed page histories that belonged to the site in the past. The precision of the site reconstruction can be enhanced by utilizing topological information preserved in the past content of site-map pages if they existed. Many Web sites include site-map pages designed to help users navigate sites. Utilizing the site-map page history could help to detect transient pages that have not been discovered by the above crawling approach and thus minimize the page error, as well as it could help to more precisely determine the actual time points of page creation and deletion within sites (timestamp error for whole pages).

PAGE TEMPORAL ANALYSIS

Page temporal analysis is the study of page content over time. Its results should be particularly useful if pages are associated with specific objects such as companies, institutions, persons or other entities. Understanding the temporal characteristics of a page over a long time frame can shed light on the associated objects or on other information appearing on the page. For example, if certain content occurred for a long time on a page which was updated frequently and regularly, then we can treat the content in a different way or with a different level of trust than if it occurred on a page that was generally static or even obsolete. A similar idea applies to a page devoted to a specific topic vs. a page that deals with many varying topics throughout its history. In other words, page temporal analysis can be used to find temporal context for information from the past. Having determined the context, it is possible to better understand the connection between Web pages and their transient content as well as to identify pages most relevant to target objects.

When mining the histories of Web pages for real-world information, we must distinguish between the valid time and transaction time of events, both of which are often used in the database research. The valid time of an event is considered as the time at which the event occurred in the real world. The transaction time is the time at which the information about the event was stored in a database or, in our case, added to a certain Web page. It can be estimated by searching the page history for the earliest occurrence of the content related to the event (Jatowt, Kawai, & Tanaka, 2007). The valid time, on the other hand, can be detected from temporal expressions appearing in the content of past page versions. This would require using special taggers and resolvers of temporal expressions in text. In addition, techniques such as the one described by Bar-Yossef, Broder, Kumar, and Tomkins (2004) could be applied for classifying page content as current or obsolete.

Next, we present a simple framework for analyzing page histories. After page history reconstruction, HTML tags, scripting code, and multimedia objects are removed from available page versions. Vector representation is then created for textual content of the past versions using a weighting method such as a term frequency. Let $\boldsymbol{V}=(\boldsymbol{v}_1,\boldsymbol{v}_2,..,\boldsymbol{v}_n)$ denote the sequence of vectors of the consecutive page versions, where $\boldsymbol{v}_j$ is the vector of a page version at time point t_j ($t_1 \le t_j \le t_n$). Next, the contents of the neighboring versions are compared with each other using a change detection algorithm such as *diff*. Added content appearing in the page's history is thereby found. All changes in each version are then grouped together and represented as a change vector. Consequently, a sequence of change vectors is obtained, $\boldsymbol{C}=(\boldsymbol{c}_{(1,2)},\boldsymbol{c}_{(2,3)},..,\boldsymbol{c}_{(n-1,n)})$, where $\boldsymbol{c}_{(j,j+1)}$ is a vector for an added-type change obtained by comparing page versions $\boldsymbol{v}_j$ and $\boldsymbol{v}_{j+1}$.

The content of past versions can be compared against any query containing terms describing given topic of interest. In order to do so, at each selected time point, a query vector, $\boldsymbol{q}_j$, is constructed by assigning uniform weights to all query terms. The sequence of query vectors is denoted as $\boldsymbol{Q}=(\boldsymbol{q}_1,\boldsymbol{q}_2,..,\boldsymbol{q}_n)$. Different values can be assigned to $\boldsymbol{Q}$ at different time points to reflect changes in the chosen topic of interest. Otherwise, the query vector is made static by having the same content at all times. To measure the relationship of past page content to the query topic, the similarity between $\boldsymbol{V}$ and $\boldsymbol{Q}$ is calculated using a cosine similarity measure. In result, the sequence of similarities is obtained: $\boldsymbol{sim}(\boldsymbol{V},\boldsymbol{Q})=(sim(\boldsymbol{v}_1,\boldsymbol{q}_1),sim(\boldsymbol{v}_2,\boldsymbol{q}_2),..,sim(\boldsymbol{v}_n,\boldsymbol{q}_n))$, where $sim(\boldsymbol{v}_j,\boldsymbol{q}_j)$ is the cosine similarity between the vector of past version $\boldsymbol{v}_j$ and query vector $\boldsymbol{q}_j$ (Figure 3). Similarly, the sequence of similarities between the vectors of the changes and the query vectors is calculated, $\boldsymbol{sim}(\boldsymbol{C},\boldsymbol{Q})=(sim(\boldsymbol{c}_{(1,2)},\boldsymbol{q}_2),sim(\boldsymbol{c}_{(2,3)},\boldsymbol{q}_3),..,sim(\boldsymbol{c}_{(n-1,n)},\boldsymbol{q}_n))$, where $sim(\boldsymbol{c}_{(j,j+1)},\boldsymbol{q}_{j+1})$ is the cosine similarity between change vector $\boldsymbol{c}_{(j,j+1)}$ and $\boldsymbol{q}_{j+1}$ (Figure 4).

First, a change frequency can be defined (Equation 1).

$$CF = \frac{fc}{n} \tag{1}$$

Here, *fc* is the number of non-zero elements in $\boldsymbol{C}$. Another measure called a change degree indicates the average change size of a page (*size(a)* denotes the size of element *a*).

Figure 3. Similarity calculation between the sequence of version vectors and the sequence of query vectors

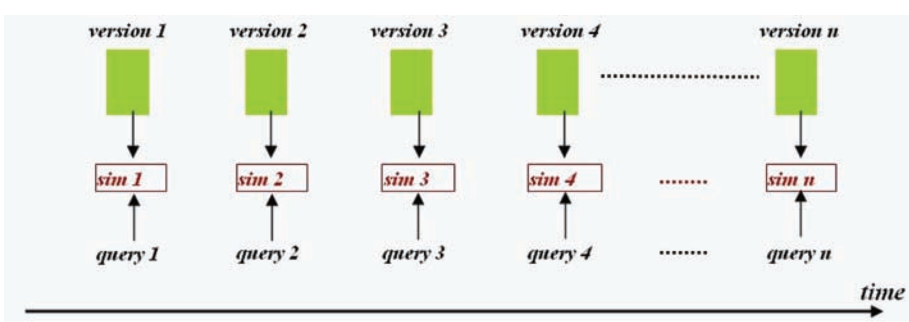


Figure 4. Similarity calculation between the sequences of change and query vectors; changes are depicted as small rectangles inside page versions

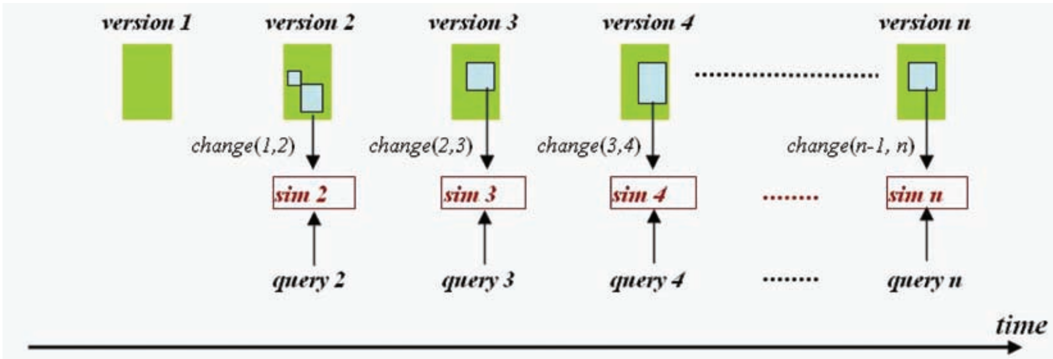


$$CD = \frac{\sum_{j=1}^{n} \frac{size\left(c_{(j,j+1)}\right)}{size\left(v_j\right)}}{n} \quad (2)$$

Besides these simple measures, the long-term relevance of a page to the query topic can be calculated. It is expressed as the weighted average of the elements of ***sim***(***V***,***Q***) by taking into account the duration of page content over time (Equation 3).

$$TR = \frac{1}{\sum_{j=1}^{n}\left(\alpha_{j+1} * \left(t_{j+1} - t_j\right)\right)} \sum_{j=1}^{n}\left[\alpha_{j+1} * sim\left(v_j, q_j\right) * \left(t_{j+1} - t_j\right)\right] \quad (3)$$

A page is considered relevant if its content overlaps with the sequence of query vectors during a large portion of a chosen time period. Using this approach, we can estimate the degree of page relevance to any topic within a given time frame. As the recent content is often likely to be more important, Equation 3 is adjusted by applying a weighting scheme depending on the age of page versions.

$$\alpha_j = e^{-\lambda\left(t_{now} - t_j\right)} \quad (4)$$

In addition, the long-term topic stability of a page can be computed by detecting the average similarity between consecutive past versions over time (Equation 5).

$$TS = \frac{1}{\sum_{j=1}^{n}\left(\alpha_{j+1} * \left(t_{j+1} - t_j\right)\right)} \sum_{j=1}^{n}\left[\alpha_{j+1} * sim\left(v_j, v_{j+1}\right) * \left(t_{j+1} - t_j\right)\right] \quad (5)$$

The long-term relevance and long-term topic stability are calculated considering the whole page content in the past, including the static content (the content that did not change between consecutive page versions). In contrast, we can compute a measure showing the degree of page updating based on the amount of changed content over time that is related to the query (Equation 6).

$$TRC = \frac{1}{\sum_{j=1}^{n}\left(\alpha_{j+1} * \left(t_{j+1} - t_j\right)\right)} \sum_{j=1}^{n}\left[\alpha_{j+1} * \frac{sim\left(c_{(j,j+1)}, q_{j+1}\right)}{t_{j+1} - t_j}\right] \quad (6)$$

A combination of different measures can also be used. For example, the measure of the temporal quality of a page is based both on the relevance of the changed content over time to the query topic and on the size of the changes:

$$TA = \frac{1}{\sum_{j=1}^{n} \alpha_{j+1}} \sum_{j=1}^{n} \left[\alpha_{j+1} * \frac{sim\left(c_{(j,j+1)}, q_{j+1}\right)}{\left(t_{j+1} - t_j\right)} * \frac{size\left(c_{(j,j+1)}\right)}{size\left(v_j\right)} \right] \tag{7}$$

According to this measure, a page is more attractive from the viewpoint of the query topic if its changes were relevant to that topic and if they were relatively large. Small changes are usually less likely to be attractive than large ones. Additionally, the temporal quality of the page is higher if the page was modified often in the past. In general, the greater the number and the larger the size of related changes that occurred within short time periods, the higher is the attractiveness of the page. The page temporal quality can be used to identify candidate pages for mining. Naturally, the precision of results depends on the amount and characteristics of the input data that is on the size of errors resulting from the history reconstruction process.

Finally, the trend of page relevance to query can be measured by fitting a regression line to the historical plot of the similarity between page content and query vectors. This allows for estimating the long-term change direction of the page relevance. A rising trend would mean that the page content becomes closer to the query topic.

TEMPORAL SUMMARIZATION

Document summarization is a well-known text mining task. Automatic summarization of Web pages aims at creating compact versions of Web documents that would contain only the most important content. Traditionally, summaries were constructed from static snapshots of Web pages (Berger & Mittal, 2000; Buyukkokten, Garcia-Molina, & Paepcke, 2001; Delort, Bouchon-Meunier, & Rifqi, 2003). However, as pages are dynamic, their content is often changed. In this section, we briefly describe the concept of temporal summarization which is the extension of the traditional summarization task into the time dimension (Jatowt & Ishizuka, 2004a, 2004b; Jatowt & Ishizuka, 2006). It is used to summarize temporal versions of Web documents in order to provide information on important content, hot topics or popular events described in pages over time. Web users are often overloaded with large amounts of data. Automatic temporal summarization would help them in discovering salient information from parts of the past Web such as histories of pages or their collections.

Following the classical division of document summarization research, two types of temporal summarization can be distinguished: single- and multi-page temporal summarization. Single-page temporal summarization attempts at capturing salient content that occurred on a page over a certain time period. The summary should thus reveal main page topics during a predefined time frame. On the other hand, in multi-page temporal summarization, multiple snapshots of a topical collection of pages are analyzed for changes over time. The summary should reveal important events or concepts that occurred in a given topical area over time. The key issue in this type of summarization is gathering pages which are up-to-date and related to the target topic so that a reliable and consistent topical collection can be synthesized. Below we discuss the multi-page temporal summarization in more detail.

Multi-page Temporal Summarization

Web collection for multi-page temporal summarization can be obtained in several ways; for example, it can be created from a user-provided set of related Web documents that she or he usually revisits for fresh information or it could be downloaded from existing Web directories. While Web directories group topically related Web documents, they provide only a limited number of categories. In a more flexible way, the collection could be synthesized by filtering search engine results based on the analysis of their temporal characteristics such as long-term relevance or temporal quality. Naturally, duplicate pages should be discarded in this process. After the initial set of topically related pages is ready, it is extended in time by reconstructing page histories for a chosen time period.

In the following step, textual data is extracted from the accumulated past versions. Then, an extractive type summarization algorithm is used to detect useful sentences for constructing a summary. First, so-called long-term scores are calculated for all terms by comparing terms' distributions in documents over time. These scores are later used to identify important sentences to be included in the summary. We propose two approaches for the long-term score calculation. One uses a sliding window that is sequentially moving through the temporal collection to search for bursts of terms in added or deleted content in the collection (Jatowt & Ishizuka, 2004a). Any terms that were added to or deleted from many pages in the collection at around the same time have high values of the long-term scores. Another approach to the calculation of long-term scores is based on the analysis of term frequency plots. The parameters of term frequency plots such as variance, slope of a regression line and intercept are calculated and compared for identification of salient terms (Jatowt & Ishizuka, 2004b). The terms with outstanding features, such as the ones with upward trends or high variance would be then scored highly. More details on the both term scoring methods can be found in Jatowt and Ishizuka (2004a, 2004b) and Jatowt and Ishizuka (2006).

After the long-term scores of terms are computed, the summarization system searches for sentences suitable for constructing the summary. Sentence selection is based on analyzing plots of the terms that have the highest long-term scores. The plots are examined to identify intervals with the closest match to the shape of an ideal plot. For example, the system may search for a time period where the frequency plot of a term has a shape that most resembles the ideal shape in which the plot suddenly increases and remains at a relatively high level over a long time. Such a plot shape may indicate the onset of an important event represented by the term. Thus, sentences containing the term are extracted from the collection within the selected time period. The system tries here also to maximize the number of different terms with top long-term scores in the selected sentences. Lastly, after the predefined number of sentences is extracted, the system orders them based on their timestamps and relative locations in their original page versions. Each sentence may also have a link to its page version added to be used in case users wish to obtain more details. Furthermore, a number of additional heuristics may be used to increase the coherence and readability of the final summary, for example, by inserting explanatory content or by modifying or reordering the selected sentences.

Discovering Object Histories

Related to temporal summarization is object history reconstruction. Objects are defined here as higher level concepts and abstractions that represent persons, institutions, ideas, organizations, and so forth. Objects can be represented by groups of related words or n-grams. Thus, object histories could be modeled using the histories of the representative terms and their inter-relationships. Time points of changes and the durations of terms' occurrences on pages would provide clues about the timing of events related to objects represented by these terms.

Object's history should be most accurate if it has been derived from a source that directly represents the object (e.g., company homepage, personal blog). The relationship between the page and objects discussed on this page can help in understanding the content related to the objects. In general, contextual information about objects can be derived from the characteristics and topical scopes of analysed pages. Furthermore, the co-occurrence of similar information among different resources increases its trustworthiness as well as helps to better determine the starting and ending points of events. The larger is the number of different data sources devoted to an object, the more reliable and accurate the discovered knowledge should be.

A possible example of object history reconstruction is an automatic creation of personal bibliographies or their parts. There is much personal data published on the Web. For example, employment data is sometimes reported on company or personal Web pages (e.g., on blogs), and other personal information can be found. This information could be collected and processed to construct biography parts.

By analyzing semantic and temporal clues derived from past Web content it could be possible to improve the detection process by employment of various heuristics. For example, the temporal information derived from the chronological ordering of events reported on past pages might help in understanding the events and may provide hints for a further search. One such possible heuristic is the detection of person's employment dates. Suppose that at some time point a person's name was removed from the page of some laboratory. Then, the system could search for the page of another institution that reported hiring the person at around that time. Note, however, that there might be certain latency between the actual events and their reports in the Web (i.e., valid and transaction times).

BROWSING PAST WEB

Apart from mining the content of the past Web, it is important to have a tool that allows for viewing data in detail, for example, in order to manually inspect the data from the viewpoint of discovered results. Such a tool should be intuitive, easy to use and possibly resemble similar applications used for the current Web. In this section, we describe the framework for a past Web browser (Jatowt et al., 2006) that supports browsing and navigation in the past Web. A browser built using this framework would be a client-side system that downloads, in a real time, past page snapshots from Web archives for their customized presentation. Such a browser would enable viewing the evolution of pages and browsing the past structures of the Web.

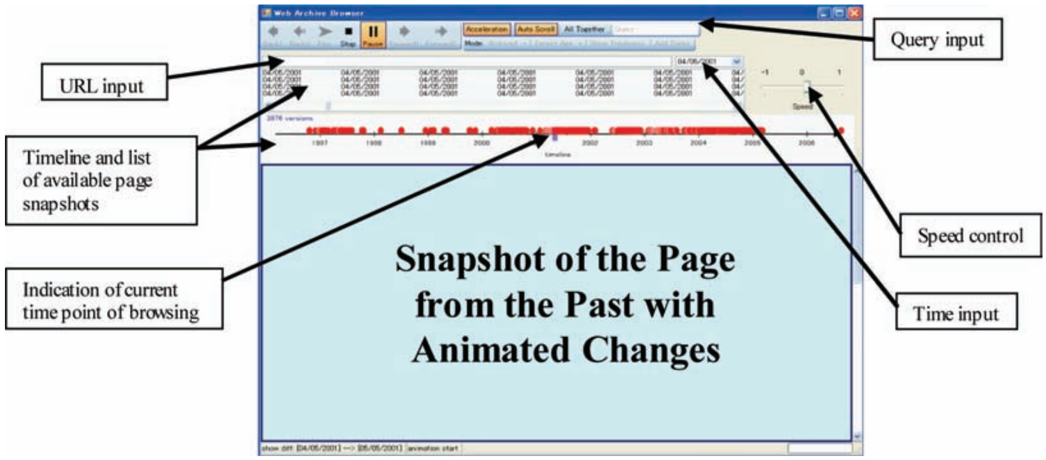
The proposed browser integrates histories of Web pages with their present versions and has a standard functionality of a traditional browser for the live Web. Consequently, browsing the live and past Web can be done almost at the same time. Thanks to this, users browsing the live Web can access the histories of viewed pages in case they need to find some content from the past, observe the page evolution or, simply, to access the latest page snapshot if the present page cannot be properly viewed due to any reasons such as a server failure.

Browsing

Two basic types of browsing are distinguished here: vertical and horizontal. The former means browsing different pages around a certain point of time by following links, while the latter means viewing past snapshots of a single page along the time direction, that is, browsing the past Web in a horizontal direction. A mixture of both kinds of browsing enables users to traverse the past Web both in time and space dimensions.

To start the horizontal browsing, the URL of a page and a point of time have to be provided. The browser fetches a page snapshot whose timestamp is closest to the user-provided time point. Next, the browser automatically downloads the following page snapshots and displays them in a passive manner. This type of viewing results in a minimum user interaction, because page snapshots are presented to the user one by one, like in a slideshow, with a certain delay predefined for each snapshot. As when watching a video, the user can pause or stop the motion, enabling the

Figure 5. Past Web browser



detailed examination of the currently presented snapshot or following its links. Besides, the user may enter a new date or a different URL to make a jump to another snapshot. In addition, a timeline is automatically constructed and displayed above the page content (Figure 5). It shows the distribution of page snapshots indicating the points of time for which snapshots are available. The currently viewed snapshot is indicated in the timeline by a blue rectangle. The information provided by the timeline prevents users from being lost in the hyperspace of the past Web by informing them about the current time point of browsing and the overall distribution of snapshots. At the same time, it is also a navigation tool thanks to which users can make a jump to any page snapshot simply by clicking on any point on the timeline. The timeline can be also zoomed to provide the more detailed view. Besides the timeline, the clickable list of all page snapshots together with their timestamps is also displayed (Figure 5).

Horizontal browsing is enhanced by a page presentation in which content changes are detected and emphasized. Keeping in mind the large size of the past Web, with lots of static, redundant data, the most effective method for horizontal browsing seems to be the one using change visualization. We think that changed data is the most important in page histories and that enhancing horizontal browsing with the change indication can portray page evolution and, in addition, help reduce the amount of browsing needed, especially in the case of static (unchanging) pages. Both content additions and deletions between neighboring page snapshots are then detected using a change detection algorithm and emphasized to indicate the content variance in pages. This enables users to spot not only the added content in consecutive page snapshots but also to identify the removed one. However, effectively showing both change types in a combined view on a single page would be difficult, especially in the case of large and overlapping changes. Thus, we propose using animation effects in order to efficiently show both change types. The change presentation algorithm displays the changes gradually, in the form of animation. Content that was deleted in the page history first blinks for a certain time period and then disappears, followed by the inserted content that first appears on the page and then blinks for a short time. Page snapshots are processed in this way line by line from left to right and from top to bottom. Content that was static between consecutive snapshots remains displayed on the page. After the page transition between two consecutive page snapshots is completed, the browser waits a predefined time period with the latter page snapshot displayed and then it proceeds to analyze the following page snapshot. The user can control the speed of the presentation using a slider provided in the top-right corner of the browser (Figure 5). Besides, as sometimes page snapshots may be too large to be shown at once, a user can choose between the automatic scrolling option and the option of displaying only the top part of page content.

Animation of changed content results in a smooth transition between sequential page snapshots. By animating changes user's attention is drawn to the changed content. In addition, changes are also highlighted by different colors to increase their visibility. However, for simplicity, in the case when the amount of change in a page snapshot is higher than the predefined threshold, no animation is done and changes are emphasized using only different background colors.

The user can stop the horizontal browsing at any time by pressing stop or pause buttons in a similar way to video players. Next, she or he can view the currently displayed page snapshot in detail or follow any link. Upon clicking on a link, the browser loads the snapshot of the linked page that is closest in time to the one being currently viewed and, after a short time period, it automatically starts the horizontal browsing on the new page.

The browser is also equipped with two back and two forward buttons to enable navigation in the space as well as in time dimensions. Besides, there is an additional navigation mechanism provided (automatic jumping facility). It enables the browser to skip periods in the page history during which the content did not change or did not change much. When this functionality is switched on, the browser displays only those page snapshots that contain more than a certain amount of change. This enables faster viewing of page evolution by omitting changeless periods.

Finally, a search option enables users to specify queries for filtering changes. If a query is issued, only the changes that contain the query terms are animated. Other changes are treated as static content and thus are not animated. This browsing style results in the filtered view of page history. Users can thus observe page histories from the viewpoint of topics that they are interested in. For example, a newswire page history could be browsed for information about "Iraq" or "presidential election" over selected time periods.

Related Research and Future Work

Visual Knowledge Builder (VKB) (Shipman & Hsieh, 2000) was an early proposal of an application that provides a mechanism for enabling history navigation in private hypertexts. The objective was to allow users to play back the history of a hypertext for witnessing the authoring of hypertexts, understanding the context of their creation and authors' writing styles. The browser interface had some similarity to VCR players.

WERA[3] (Web ARchive Access) and Wayback Machine[4] are applications for accessing Web archives. WERA supports time and URL input for specifying a particular page snapshot. There is a timeline provided showing the available page snapshots and indicating the currently browsed one. Users can view the consecutive page snapshots by clicking arrows in the timeline.

Wayback Machine is a Web-based interface to the Internet Archive. After a user inputs a URL, optionally with a time period specified, links to the available page snapshots are listed on the "directory" page. The user can then click on any snapshot to view its content or follow its links if the linked snapshots are also stored in the archive. The directory page indicates also page snapshots that contain changes by marking them with asterisks. Horizontal browsing using Wayback Machine is difficult, as users need to access the directory page each time if they wish to view other snapshots.

Both the Wayback Machine and WERA are server-side applications designed for single Web archives. Our proposed browser is a higher-level, client-side application that allows for the usage of multiple past Web repositories at the same time, thus, enabling browsing of the past Web rather than browsing single archives. Browsing the past Web is also facilitated by combining passive, automatic page viewing together with a change presentation. The framework has also functions that minimize the user effort and time required to find specific information in the past snapshots of pages. In addition, navigation mechanisms are provided to enable traversal of the link structure of the past Web. Testing the browser built on the proposed framework demonstrated its usefulness (Jatowt et al., 2006). Users were able to move freely in the past Web, find desired information and relatively easily obtain an overall view of pages' evolution.

In a multi-authoring area, an interesting application has been recently proposed for effective visualization of histories of wiki pages (Viégas, Wattenbeg, & Dave, 2004). It allows viewing contributions of different authors and their persistence over time as demonstrated on the example of Wikipedia pages[5].

There are several possible directions for expanding the proposed framework. For example, location-based browsing would allow a user to select a certain area on a page and then view its evolution over time, provided that the structure of the page did not change substantially. This would limit the presentation to only those changes that occurred in the selected area, for example, in the sports section of a newswire page. Next, links on visited snapshots could be annotated with timestamps of page snapshots that will be accessed when following these links. Thanks to it, a user would know how much time jump she or he is going to experience upon clicking on a certain link. Lastly, a comparative past web browser could enable comparison of histories of two or more pages highlighting their common or similar parts.

CONCLUSION

The Web has become nowadays a major means of communication and an important information repository. Due to its dynamic, ever evolving character, much of the content regularly disappears from the live Web and can only be accessed through Web archival repositories. Knowledge discovery from past Web is a challenging and promising research direction. Mining the content of the past Web differs from traditional Web content mining and thus requires a novel approach. In this chapter, we have described several issues related to mining data in Web archives. First, we provided the outlook on the data collection and preparation steps and emphasized their importance. Next, we demonstrated the methodology for determining page temporal characteristics as a source of contextual information for describing pages and their transient content. Then, data summarization and object history detection were described as examples of mining tasks on the past Web. Finally, we proposed the application for browsing and navigation in the past Web.

Chapter 8.16

New Forms of Deep Learning on the Web:
Meeting the Challenge of Cognitive Load in Conditions of Unfettered Exploration in Online Multimedia Environments

Michael DeSchryver
Michigan State University, USA

Rand J. Spiro
Michigan State University, USA

ABSTRACT

We claim that the Web has the potential to be a quintessential multimedia environment for complex learning, particularly in ill-structured domains. This chapter explores the cognitive load considerations associated with several aspects of deep and extended learning on the Web. We also propose the need for a reconceptualization of Cognitive Load Theory for comprehension and learning in more ill-structured conceptual arenas. This reconceptualization emphasizes the need for learning approaches that promote flexible knowledge assembly through processes of organic, reciprocal, and deep Web learning.

DOI: 10.4018/978-1-60566-158-2.ch008

INTRODUCTION

The Web has the potential to become a quintessential multimedia learning environment. Both formal and informal learners are increasingly turning to the search engine as their primary source of information. For example, college students regularly use the Internet and commercial search engines (e.g., Google) before, or in lieu of, local library resources (Griffiths & Brophy, 2005; Jones, 2002; Thompson, 2003; Van Scoyoc, 2006). At the same time, the content provided to them on the Web is presented in multimedia form, often comprising various combinations of text, data, pictures, animation, audio, and video, of differing levels of interactivity. These myriad forms of information all battle for learner attention and consideration.

The second author argued that this migration away from traditional information resources to Web mediated multimedia learning environments is ushering in a revolution in thought, a New Gutenberg Revolution (2006a, b, c, d, e). He outlined how, given the dramatic increases in the speed with which information can be accessed, the increasing well directedness of search (due to more advanced search algorithms, data organization, and searcher skill), and the *de facto* assumption of "ambient findability" (Morville, 2005), the Web is becoming a more fertile knowledge landscape than man has ever known. Consequently, the Web is particularly well suited to support *deep* learning for subjects and concepts that are complex and ill-structured; the kind that we seem to be finding more and more of in the world everyday. These ill-structured domains of knowledge demonstrate an inherent *irregularity* of conceptual application across instances and contexts (for discussion of the special qualities of learning in ill-structured domains, see Spiro & DeSchryver, in press; Spiro, Vispoel, Schmitz, Samarapungavan, & Boerger, 1987; Spiro, Feltovich & Coulson, 1996).

In order to harvest information from this landscape in the most effective and meaningful ways, learners will need to explore the Web with a Post-Gutenberg Mind. This involves searching with *advanced Web exploration* techniques and an *opening mindset* that together result in advanced knowledge acquisition that goes well beyond the cursory and fact based searches most common to learning on the Web (Kuiper, Volman & Terwl, 2005). The knowledge structures acquired by a Post-Gutenberg Mind will be tailored assemblages that are contextualized, interconnected, and flexible, enabling the everyday creativity necessary to succeed in a world increasingly driven by complex and rapidly changing information.

Sounds great, doesn't it? Well, as it turns out, not everyone is prepared to use the Web to learn like this right now. In fact, we do not really know precisely how deep learning on the Web occurs. As such, it is imperative that we begin to thoroughly examine the phenomenon. We need to better understand the specific ways that Post-Gutenberg learning will manifest itself. What specific affordances and aspects will enable deep Web learning of ill-structured concepts? How will they differ from the characteristics of traditional learning? How will we best prepare learners to maximize the benefits of deep learning on the Web? What will be the cognitive load considerations for learning that is of such depth and complexity?

With these questions in mind, we recently embarked on an inquiry to investigate the emergent aspects of Post-Gutenberg learning for an advanced Web learner in an ill-structured domain. In this study, we documented the decision-making, knowledge construction, and general learning reflections of an advanced Web searcher who examined the subject of climate change through deep and extended Web learning. The data were collected from a baseline mind-map of existing knowledge, extensive notes taken by the learner during each session, the parallel use of Clipmarks (an online tool that allows for portions of Web resources to be saved, tagged, annotated, updated, and retrieved in multiple ways), and corresponding updates to the mind-map. A detailed analysis of the data collected from this study has provided a better picture of what Post-Gutenberg learning may look like. And, while we do not claim any generalizability from the results of this demonstration case study (i.e., we sought to demonstrate what *is possible* not *what is*), several interesting phenomena emerged that are worthy of continued scholarly examination. (For a more detailed presentation of the theoretical implications of this study, see Spiro and DeSchryver, in preparation; for a more detailed accounting of a full list of deep Web learning aspects and their derivation, see DeSchryver and Spiro, in preparation.)

One of the primary considerations that surfaced was whether this form of advanced knowledge acquisition would be, in general, too challenging for the learner. Cognitive Load Theory has provided an excellent framework with which to address these questions (e.g., see Sweller, van Merrienboer & Paas, 1998; van Merrienboer & Sweller, 2005). Therefore, this chapter focuses on the cognitive load implications of deep Web learning in ill-structured domains that were identified during our investigation. First, we present an overview of deep Web learning. Second, we review the basic assertions of Cognitive Load Theory and suggest the need to reconceptualize cognitive load as it relates to the goals of learning in ill-structured domains and the skills needed for the requisite flexible knowledge acquisition. Finally, we discuss the cognitive load considerations for specific aspects of deep learning in ill-structured domains on the Web, the adjunct online tools that support them, and related motivational developments.

DEEP WEB LEARNING AND THE NEW GUTENBERG REVOLUTION

Post-Gutenberg learning holds the promise for increasingly complex, but cognitively manageable knowledge acquisition, through learning and instruction that better fits the contours of the world and knowledge about that world. Among other things, it may provide answers to many of the greatest challenges to learning complex and ill-structured topics by supporting the development of the type of adaptive knowledge application that is increasingly important in the world today.

The foundation of Post-Gutenberg learning is the dramatically increasing high speed of connection and access to effectively unlimited Web resources. The former has resulted from technical advancements in hardware and software (e.g., search engine and data-mining algorithms that result in more precise results); enhanced techniques for information organization, such as tagging *en masse*; and, increased integration that advanced Web learners are demonstrating with information search, access, and evaluation (DeSchryver & Spiro, in preparation; Tremayne & Dunwoody, 2001). The seemingly unlimited nature of information available on the Web is described by Morville's (2005) notion of ambient findability, or the crossroads of ubiquitous computing and the Web, in which we can find anyone or anything from anywhere at anytime. This breadth and depth of knowledge provides a multiplicity of perspective, context, interconnectedness, and points of entry that are essential to learning complex, ill-structured concepts.

Most current Web-based learning is rather cursory and fact based (Kuiper, Volman, & Terwel, 2005), therefore new skills and approaches are needed to in order for Post-Gutenberg learning to develop. Foremost among these are the ability to search using *advanced Web exploration* techniques and with an *opening mindset* that promote more wide ranging searches that go well beyond finding facts or "answers" by using just simple Google results or embedded hyperlinks. These wide ranging searches unfold using learner-initiated, complex, reciprocally adaptive (LICRA) techniques that capitalize on the Web's affordances for deep learning by permitting maximally unfettered and externally oriented nonlinear traversals of knowledge spaces. We use "externally oriented" in the sense that the learner's next steps can be strongly influenced by the content that is encountered in Web explorations, rather than operating with more internally driven or "top-down" expectations and learner guidance, such as that provided by embedded and precompiled hyperlinks or simple sequential review of Google result lists. The learner creates their own search phrases based on information they encounter on the Web, either through employing specific ideas from the current page as new search phrases, or by conceptualizing novel search phrases based on recent activity, past experience, and the related momentum Web learning affords. These techniques result in learner controlled non-linear movement through the conceptual landscape, where the learner creates "undefined" connections between resources. In our recent investigation, this LICRA type searching led to several more conceptual breakthroughs than did the use of existing embedded hyperlinks (DeSchryver & Spiro, in preparation).

While performing these searches, learners much be prepared for discovery, complexity, change, and creativity (Spiro, 2006a) and see the Web as *open* to their exploration. When reflected in LICRA searches, openness allows the learners to see the key phrases or ideas in the current document (text, animation, audio, or video) that merit a new branching inquiry. An opening mindset also includes being open to using the Web for more than "basic" Web searches. At Google alone, searches through images, videos, blogs, scholarly materials, books, and news are separately available. Searching with these individual engines provides several unique knowledge landscapes, variant representations, and differing perspectives based on the identical search phrase. Finally, an open mindset is essential to taking advantage of the myriad opportunities for unexpected and *serendipitous* learning on the Web.

Together, these foundational components to deep Web learning undergird *virtual simultaneity*, defined as the condition "in which many things are [simultaneously] being considered in the context of each other and in which *conceptual wholes greater than the sum of the parts* can form" (Spiro, 2006e, p. 2). The simultaneity is virtual, not temporal, in the sense that it is within a functioning cognitive space. This is a core aspect for Post-Gutenberg learning, which, in concert with cognitive spreading activation, allows connections to be noticed that would not be noticed otherwise. It facilitates multiple conceptual comparisons and contrasts, allows for increasingly complex but cognitively manageable learning, provides an acceleration of the acquisition of experience, and develops open knowledge structures that can be tailored to new contexts. The speed increases outlined above have resulted in a learning environment where virtually simultaneity is not only possible, but may be common.

While very little empirical evidence exists for this emergent learning phenomenon, our recent demonstration case study provided evidence of the type of learning we describe above. For instance, the concept of virtual simultaneity was exemplified well in an early session of the study. While learning about climate change, the subject navigated quickly through successive articles in the NY Times global warming section, scanning articles about the New Hampshire ski industry, autobahn speed limit considerations, carbon sequestration, and Pacific Islanders' concerns over rising ocean water. Though seemingly unrelated, this progression of articles one after another lead directly to the learner recognizing and documenting the importance of "selfishness" and "local recognition" as two important concepts in his understanding of climate change. We submit that the speed with which information can be accessed and the precise targetability provided by modern search engines on the Web directly facilitated such rapid conceptual development in a way that no other medium could. In this case, there was clearly a *loose* connection made among what were otherwise *heterogeneous* resources.

Two specific benefits arise from such loose associations and resultant conceptual development. First, the learner begins to appreciate the *conceptual variability* inherent to ill-structured domains. It becomes clear that though similarities exist across the disparate examples, they are not exactly the same. The nuances of New Hampshire residents' concerns with its ski industry cannot be mistaken for the concerns of Pacific Islanders'; these examples are not interchangeable. Fast nonreductive conceptual induction safeguards the conceptual rough edges that are desirable when learning concepts in ill-structured domains. These rough edges directly facilitate the second benefit: *flexible use.* When faced with situation specific need for the concept of selfishness or local recognition, the learner will be well prepared to select an appropriate prototype example (or examples) for application, based on both the similarities and differences that have been preserved among the candidates.

The development of several even more complex knowledge structures related to climate change were also apparent in our study. Among them, consider the concept of carbon markets, about which the subject had minimal prior knowledge at the onset of the study. However, during early research sessions, a complex understanding of carbon markets developed quickly, including the varying effects of mandatory and volunteer cap and trade systems; the Chicago Climate Exchange; related government inclinations (from the United States, European, and Chinese governments); and corporate interests. The subject considered the benefits and drawbacks of carbon markets, from the innovations that were directly credited to Clean Development Mechanism applications, to the inherent waste that carbon market critics argued. Ideas about why (typically anti-regulatory) US business interests are actually calling for more federal regulation in this arena were considered, and proposals that markets may not be able to cure the problem, given some assertions that climate change is the "greatest market failure" ever, were examined.

The implications of this specific example for deep learning in an ill-structured domain are two-fold. First, imagine trying to gather the resources to "instruct" a learner about the topics outlined above, and then completing this task in just a few hours. Any reasonable analogous approximation of the time necessary to replicate this information with traditional resources would be *many* times greater. Examination of a knowledge structure this complex and ill-structured cannot otherwise be accomplished without a learning environment like the Web, its specific affordances, and the skills and mindset outlined above. However, even more important was the evidence that this knowledge was later *flexibly reassembled*. In one of the final research sessions, in the context of how to change individual behavior to address climate change, the learner recombined several of the ideas about carbon markets with concepts from elsewhere (e.g., capitalism and economics) to propose the use of cap and trade systems for individual energy consumption. When considering the impact higher demand, lower supply energy may have on home energy use, the subject adapted the concept of lower effective per-unit carbon costs from carbon markets (and how mandated versus volunteer caps impact the level of incentive provided), with the profit considerations of utility companies, to propose how the adoption of a "personal" cap and trade system for home energy would differ from those currently in place in industrial carbon marketplaces. This thought experiment served to both strengthen his understanding of industrial cap and trade systems (through revisitation of the related ideas) and provided key insights into some of the economic considerations needed to better understand issues related to his inquiry into individual climate change behavior. A more detailed accounting of both learning experiences is provided in DeSchryver & Spiro (in preparation). In sum, this demonstration case study suggested a clear relationship between the way that the material about carbon markets was learned and how it was later flexibly applied.

The level of complexity varied widely for the ideas encountered by the subject over the course of our study. However, he examined several more broadly ill-structured concepts, identified their inter-relationships and integrated them into an evolving and complex knowledge structure of climate change. These included:

- The role of capitalism/consumerism in climate change
- The mixed messages of corporate climate change agendas (e.g., Wal-Mart)
- The ever-changing nature of religion as it relates to climate change, and how "religious" perspectives often differ from the theological and philosophical considerations

- The educational implications of changing climate related behavior
- The complex relationship between climate change mitigation and adaptation
- Technology as both a climate change "cause" and "cure"
- The nascent eco-biz industry and related alternative fuel considerations
- The role and impact of international agencies (e.g., IPCC) and studies (e.g., Stern Report) in climate change
- Why the US and Europe have decidedly different approaches to climate change (both individual and governmental)
- The relationship among supercomputers, modeling, and climate change
- The role of media as it relates to climate change

It is important to note the extent to which each of these ideas interconnected with the others. For instance, the concept of religion was encountered several times. The subject developed an understanding of how both personal and institutional religious considerations shape issues related to climate change in powerful ways, and cannot be disconnected from policy and personal behavioral decisions. At the same time, these ideas demonstrated irregularity across instances, a hallmark of ill-structured concepts that differentiate them from complex, but well-structured concepts. For instance, early in the study, it was determined that several key religious institutions had begun to support policies to aggressively combat climate change. After having seen multiple examples of this positive support, the *temptation to generalize* on the part of the subject could have been very high (e.g., he could have generalized the concept that religious organizations support aggressive policies to mitigate climate change). However, a few sessions later, information about how one key religious institution had reversed its position was encountered. The ability to recognize and appreciate the irregularities that exist for concepts applied in ill-structured domains is critical, and directly facilitated by deep Web learning; learning in this way disables the temptation to overgeneralize by inculcating a mindset that "it's not that simple."

COGNITIVE LOAD THEORY

While we find the above learning outcomes impressive, it may well be that this method of learning is just *hard*, or cognitively demanding. How, then, can we ensure that more people will be able to achieve these outcomes without overwhelming cognitive demands? We will address this question through the lens of Cognitive Load Theory (CLT), a framework often utilized for just such concerns in learning.

CLT has been a leading framework for the study of human learning (e.g., see Sweller, van Merrienboer & Paas, 1998; van Merrienboer & Sweller, 2005). At the heart of CLT is a limited working memory for novel information and procedures, which demonstrates no such limitation when information is retrieved from long-term memory and related schemas (Ericsson & Kintsch, 1995). CLT assumes that long-term memory has unlimited capacity and that learning only occurs when changes in long-term memory have occurred (Kirschner, Sweller, & Clark, 2006). Cognitive load is calculated by the additive relationship among *intrinsic*, *extraneous*, and *germane* cognitive load (Paas, Renkl & Sweller, 2003; Sweller, van Merrienboer & Paas, 1998; van Merrienboer & Sweller, 2005). Intrinsic cognitive load is based on the fundamental characteristics of the material to be learned, most importantly, the number of elements that have to be considered simultaneously for successful learning (called *element interactivity*). Extraneous cognitive load is the *ineffective* load imposed by poor decision making related to the organization and presentation of information to be learned. Germane cognitive load is *effective*, in that it requires the "mindful engagement" of the learner with what is most essential to enhancing learning. Both extraneous and germane cognitive load are considered in CLT to be under the control of instructional designers. The ideas of CLT have been examined in a number of experiments that have confirmed the theory's predicted relationship between kind of load and success in learning for different instructional designs.

In recent years, these basic ideas have been developed and extended to incorporate the demands of "real-life" tasks and the complex learning they often represent (van Merrienboer & Sweller, 2005). For example, the role of "chunking" by experts in reducing the number of interacting elements, which results in lower effective intrinsic load, is increasingly of interest. CLT researchers have also begun to examine the effect of motivation on cognitive load in real-life learning and training contexts (e.g., see Pass, Tuovinen, van Merrienboer & Darabi, 2005).

Learning of the depth and complexity we describe in the section above has several cognitive load implications. Often, the total cognitive load is high. But, this heightened load should not always be avoided, given the potentially deleterious effects to learning from oversimplifying complex material (Feltovich, Coulson & Spiro, 2001; Spiro, Feltovich, Coulson & Anderson, 1989). It does no good to ignore *necessary* learning difficulty. When high cognitive loads for learning in ill-structured domains are encountered, they primarily derive from the nature of the material itself, or its intrinsic cognitive load. We have no choice but to acknowledge that this is the case, and work with it. Whereas, CLT has recently expanded and developed to address complex learning by "artificially" reducing element interactivity to reduce intrinsic cognitive load, since "understanding complex information may not be necessary or even possible in the early stages of learning" (van Merrienboer & Sweller, 2005, p. 157), we do not advocate this approach for ill-structured domains.

If intrinsic cognitive load in an ill-structured domain is high, artificially reducing the complexity in early learning is dangerous in two ways. First, with respect to the local concept, early simplifications interfere with the later acquisition of complexity (Feltovich et al., 1989, 1997, 2001; Spiro, Coulson, Feltovich, & Anderson, 1988; Spiro, Feltovich, Coulson, & Anderson, 1989). Second, such simplifications inculcate a reductive mindset, in general. In stead of simplifying complex, ill-structured material, we need to learn how to deal with it. Learning in and about ill-structured domains is hard and requires mental effort. Boiling these ideas down for simple presentation makes the ideas easier to learn (and easier to teach and assess), but does not facilitate the situation specific, interconnected, context dependent, flexible assemblies of knowledge that are necessary for successful learning outcomes.

In other situations, cognitive load may appear to be higher than it actually is. We present two reasons why this is case. First, in the following section, we revisit the concept of cognitive load and explore how it must be reconceptualized in order to better apply to ill-structured concepts, deep Web learning, and the Post-Gutenberg Mind. This reconceptualization mitigates some of the cognitive load concerns by arguing that common sources of extraneous cognitive load in well-structured domains actually represent germane load in ill-structured domains. Then, in the section thereafter, we discuss how specific aspects of deep learning on the Web may further ameliorate cognitive load concerns.

COGNITIVE LOAD THEORY REVISITED

We find the evolution of CLT to be impressive in its consideration of expertise, real-life tasks, and complex learning. However, given that in its application, CLT has primarily been concerned with "relatively well-structured procedural and conceptual domains" (van Merrienboer & Sweller, 2005, p. 156), we propose that a reconceptualization is necessary in order for CLT to apply to real-life learning tasks in ill-structured domains, especially in deep Web learning. (See also Gerjets and Scheiter (2003) for their useful suggestions about the relationship between cognitive load, learner goals, and individual processing strategies in hypertext learning environments.) We present this reconceptualization with four distinct arguments. First, we highlight how ill-structured domains and well-structured domains are dissimilar and how the goals for learning in each must also necessarily differ. Second, we outline a reconceptualized germane cognitive load that is more appropriate for learning in ill-structured domains. Third, we discuss how this reconceptualization underscores our position that *what is considered extraneous cognitive load in well-structured domains is often germane in ill-structured domains*. Finally, we argue that the Web represents a quintessential environment in which to optimize the ratio of extraneous load to germane load for learning in ill-structured domains.

Learning Goals in Ill-Structured versus Well-Structured Domains

The learning goals in well-structured and ill-structured domains are not the same. This stems from the structural differences that exist between them. Well-structured material, even that which demonstrates complexity, exhibits orderliness and regularity that underscore the goals for learning. It is always possible to present essential information or known procedures for well-structured material. Answers exist to questions posed in well-structured domains. Therefore, the primary goal for learning in well-structured domains is the construction and automation of schemas. Traditional CLT, primarily working within well-structured domains, therefore defines germane cognitive load to comprise the mental effort devoted to such schema construction and automation (van Merrienboer & Sweller, 2005).

However, the goal for learning in ill-structured domains is very different, focusing on the construction of open and flexible knowledge structures for situation specific application. This is primarily due to the *irregularity* that concepts and phenomena demonstrate across instances and applications, such that pre-specifying the conditions under which knowledge will be used is not possible. Because of this irregularity, emphasizing only the acquisition and automation of prepackaged schemas does not provide the flexible knowledge structures required; schemas alone cannot prepare learners for the wide scope of application needed, since essential information and known procedures do not exist. Since there are not specific answers with universal application to questions posed in ill-structured domains, preparing the learner for situation-sensitive development of "schemas-of-the-moment" is of utmost importance. (For a more detailed presentation of the special qualities of learning in ill-structured domains, see Spiro & DeSchryver, in press; Spiro, Vispoel, Schmitz, Samarapungavan, & Boerger, 1987; Spiro, Feltovich & Coulson, 1996.)

Germane Cognitive Load for Ill-Structured Domains

The concept of germane cognitive load must therefore be reconceptualized in order to be consistent with the learning goals for ill-structured domains. In general, we encourage mental efforts that resist oversimplification and resist reductive thinking. In this way, we advocate an emphasis on learning activities that support new constructions of indefinite numbers of situation sensitive assemblages and not retrieval of precompiled schemas or templates from long-term memory. These activities comprise a more appropriate conceptualization of germane cognitive load for ill-structured domains, and should include:

- Recognizing interconnections
- Criss-crossing the knowledge landscape
- Experiencing multiple perspectives and representations
- Testing candidate generalizations with a presumption of "it's not that simple" until proven otherwise
- Seeing patterns of context dependence
- Identifying how surprising similarities and surprising differences unfold

Recognizing that Extraneous Cognitive Load Activities in WSDs Often Appear as Germane Cognitive Load in ISDs

Based on traditional conceptions of CLT, the activities we have outlined that are crucial to learning in ill-structured domains represent extraneous cognitive load when learning in well-structured domains. As well they should. When essential information is known, or a correct procedure available (as is typically the case for well-structured material), it should be presented to learners in a way that maximizes their ability to acquire, update, and automate schemas. Criss-crossing the knowledge landscape to find essential information would increase extraneous load dramatically, wastefully, and unnecessarily.

The reverse is also true. Schema construction and automation (considered germane to learning in well-structured domains) is extraneous to the goal of flexible learning in ill-structured domains. It is equally as wasteful to construct and automate schemas in ill-structured domains as it is to criss-cross well-structured domains looking for known information. Since tailored "in-the-moment" assemblages are most germane to learning in ill-structure domains, intact schema retrieval is minimized, and any time spent constructing intact schemas is essentially wasted. In fact, use of intact schemas tends to compartmentalize knowledge in a way that works against the goals of flexible knowledge, by blocking the ability for the learner to properly recognize the inherent interconnectedness in ill-structured domains (Spiro et al., 1991). In this way, schema construction not only represents extraneous load for learning in ill-structured domains, but also directly undermines the primary process of flexible knowledge construction.

The Web is a Quintessential Learning Environment in Which to Optimize Germane Cognitive Load for Learning in Ill-Structured Domains

Our conceptualization of germane cognitive load for ill-structured domains will also appear to represent extraneous cognitive load when considered for traditional linear media. However, with hypermedia and especially now the Web, we finally have learning environments that accommodate advanced knowledge acquisition in ill-structured domains and work to make our proposed mental efforts germane. In fact, the affordances of the Web keep extraneous load *much lower* for learning activities that are specifically relevant to ill-structured domains than they would otherwise be with traditional media.

For instance, if you accept that criss-crossing non-linear irregularly interconnected knowledge is essential to learning in ill-structured domains, what better medium exists than the Web? Consider again how long it would take for a learner to find print media in a library even closely approximating the expansive and up-to-the-minute resources outlined above for climate change. Then, imagine how long it would take to begin to recognize the intricate interconnectedness among these myriad resources. The extraneous load requirements would be overwhelming with traditional media. However, on the Web, interconnectedness is inherent. What is the optimal use of cognitive load resources to recognize interconnections among disparate information resources, card catalogs and indexes, or the instant-access, fully searchable, non-linear Web? There is no comparison. The Web is ideal for learning in this way.

COGNITIVE LOAD CONSIDERATIONS FOR SPECIFIC ASPECTS OF DEEP WEB LEARNING IN ILL-STRUCTURED DOMAINS

As we have noted, many aspects of deep Web learning in ill-structured domains that are germane might, in well-structured domains or with traditional linear media, be considered extraneous, and vice-versa. In this section, we discuss several aspects of deep Web learning in ill-structured domains and how they may help to maximize the ratio of germane cognitive load to extraneous cognitive load. Again, we present these ideas as *what is possible* for deep learning on the Web not *what is* the case for everyone. Continued research that examines these phenomena more specifically will help identify the conditions under which they apply more broadly, and how to best prepare novice learners for deep Web learning in ill-structured domains.

LICRA Searches

Learner-initiated, complex, reciprocally adaptive (LICRA) searches are a core feature to successful deep Web learning in ill-structured domains. These searches promote active involvement from the learner, require heightened attention, and emphasize the need for value determination and judgment. Given this additional effort required to generate successful LICRA searches, it should be expected that associated cognitive loads are rather high. Indeed, traditional CLT often associates searching of any kind-- for information needed to complete a learning task, for solutions, or for referents in an explanation-- with extraneous cognitive load (Paas, Renkl, & Sweller, 2003; van Merrienboer Sweller, 2005).

However, consistent with the above account of how cognitive load applies to ill-structured domains, this effort represents *germane* cognitive load. LICRA searches are part of the learning process and cannot be viewed separately. When learners use a LICRA phrase, they create implicit interconnections among resources. The iterative nature of these searches also facilitates criss-crossing the conceptual landscape in order to construct a better sense of the whole. As a result, when compared to following embedded hyperlinks or scanning through a single list of Google results, these iterative search techniques promise an even greater payoff.

Extraneous cognitive load concerns about hypertext learning are somewhat ameliorated by LICRA searching, as well. The decision-making that is "required" by the visual cue of an embedded hyperlink may serve to increase extraneous load, especially if multiple links appear on the same page (DeStefano & LeFevre, 2007). This "interruptive" quality does not exist for LICRA searches, because they result from an internal, somewhat spontaneous, assignment of importance on the part of the learner. There is also some concern that following hyperlinks, especially for a long time or to "semantically distant information" (DeStefano & LeFevre, 2007, p. 1620) increases cognitive load and reduces comprehension. However, criss-crossing, or following links, either embedded or learner initiated, is a core feature of deep Web learning when learning in ill-structured domains. And, many forms of extraneous load associated with the criss-crossing supported by LICRA searches should be increasingly mitigated by the growing body of adjunct learning aids (see below) that help to manage and make explicit the choices and relationships that emerge while exploring the knowledge landscape. We also envision that as learners become more effective at LICRA searching, the "after-the-fact" ratio of germane to extraneous load will also optimize (i.e., more LICRA phrases will yield useful information and less will be "dead-ends").

It should be noted that there are well-structured skills that are necessary in order for learners to perform successful LICRA searches. For instance, using quotation marks to target exact phrases, employing Boolean logic, searching a specific site, using a tilde to return related items in a search, and using the "link:" phrase to determine backlinks, are all useful skills that should be taught to and practiced by Web users. We support the notion that the automation of schema for such skills is essential to good LICRA searching and should be done with the lowest possible extraneous cognitive load.

Serendipitous Learning

Serendipitous learning comprises an accidental encounter with seemingly unrelated or useless information that then becomes relevant. Such serendipitous learning is automatic, unconscious, and spontaneous in nature, inherently requires no conscious mental effort, and thus demonstrates a very low cognitive load requirement. While the value of making serendipitous connections between unrelated ideas is not new to hypertext research (e.g., Bernstein, Bolter, Joyce, and Mylonas, 1991), it has often been a form of "quasi-random" knowledge association, given the finite amount of information in closed hypertext systems or when just following links provided on a web page. However, in deep Web searches utilizing LICRA methods, serendipitous information can, and does, emerge at any time. The likelihood of the occurrence of serendipitous learning increases exponentially as the speed of access to information increases, as Web users search more efficiently, and as the landscape of resources available becomes, for practical purposes, unlimited. This exponential increase in potential random encounters requires no additional effort on the part of the learner, but is often significant to the learning process. Our recent research demonstrated several points at which serendipitous finds resulted in significant conceptual breakthroughs and novel interconnections of information for the learner (DeSchryver & Spiro, in preparation).

Such serendipitous learning can happen at any time on the Web, including moving "backwards" in the search process. For instance, in our recent study, it was common for the learner to open several new browser tabs during LICRA searches to accommodate multilevel iterative search phrase development. Several times, after a "stopping-point" in this process was reached, and while returning to his original search results (e.g., "backing out" of the iterative searches), the subject noticed information that did not seem relevant when it was first viewed but that was particularly useful in the context of the new information he had since encountered. This new relevance may simply have occurred as a result of the accumulated context. However, the benefits of "considering," or reviewing, information multiple times within a relatively short period, need to be explored.

Resource Evaluation

The evaluation of a Web resource for authority and accuracy typically has extensive extraneous cognitive load implications. Learners are often provided with rubrics containing several questions to answer for each Web resource they encounter. For example: Is it a personal page? What type of domain is it from? Who wrote the page? Is it dated? Is it current enough? What are the author's credentials? Are sources documented? Are there links to other sources? (see Finding, 2008, for a full and much more exhaustive list). The use of such guidelines requires very high extraneous cognitive loads. And, while such rubrics may be valuable for young or introductory learners, our recent study provided evidence that this process may become fully integrated into the learning process for advanced learners.

One reason for such integration is that the Web is full of "trusted aggregators" that reduce the evaluation necessary. For instance, the New York Times has a list of articles related to climate change. At the same time, especially in extended learning on the Web, learners will visit the same sites over and over. Subsequent visits to a trusted site (including what are often visits to topically disparate sub-nodes in the site) require no additional evaluation.

However, more significantly, we submit that the integration of resource evaluation results primarily when the learner becomes adept at seeking out multiple representations of one concept while learning about it. Through recognizing the similarities and differences among the multiplicity of resources, it quickly becomes apparent which resources are trusted and which are not, without working through a guideline of static questions about each resource. In this way, resource evaluation is *fully integrated into the learning process* for the advanced learner by an often unwitting method of *triangulation*. Each site visited not only provides new information, new contexts, new representations, and new perspectives that are germane to learning, but also tightens the criteria for filtering out resources that do not reflect the quality, accuracy or credibility of acceptable sites. From a cognitive load perspective, an extraneous load requirement has been transferred to a germane learning activity.

Blogs

The nature of the information found during deep Web learning has significant implications for the learner's cognitive load. For instance, blogs now increasingly find their way into Web search results. The casual form of information typically encountered in blogs has largely been considered useless for serious knowledge inquiry (e.g., see Head, 2007). However, we found that several categories of blogs were examined during our recent study, running the gamut from factual to opinionated. Analysis of the various types of blogs that were used, as well as their interactions with the differing stages of meaningful learning (Sheull, 1990), indicated that blogs can be quite valuable to the learning process and that the related cognitive load requirements vary.

For instance, the use of blogs in early stage learning (fact-based) does not seem beneficial. The above methods for resource evaluation require more authoritative resources for fact-finding. Though many excellent factual blogs exist and were encountered by the subject during early stage learning, most were filtered out by resource triangulation methods. It seems additional extraneous cognitive load would be required to determine the credibility of facts in a blog, whereas the triangulation techniques for resource evaluation for other more authoritative factual sites require less effort. Evaluating blogs for "facts" just does not seem worth the extra mental effort at this stage in learning.

However, during latter stages in the learning process (involving more problem-solving and abstract thinking) triangulation methods for resource evaluation valued the opportunity for "idea play" that less factual blogs provided. We submit that taking into account the speed with which ideas from different blog sites can be experienced on the Web can result in a dialogical interaction among the user and multiple blog sites. In this way, the learner can agree with some authors and disagree with others; accept some points, and discount others; all the while developing his or her own ideas through arguing, counter-arguing, and the related combinatorial idea play. In this way, the voices in blog entries are *virtually synchronized* and provide great potential for deep learning of ill-structured domains on the Web. At the same time, the extraneous load associated with early (fact-based) use of blogs is minimized, since the interactions with blogs become germane during creative knowledge assemblies. Extraneous cognitive load is also further reduced by the conversational text found in most blogs that is often easier to comprehend for the learner than other, more authoritative resources. Examples of this type of learning are provided in DeSchryver and Spiro (in preparation), where the use of blogs was directly responsible for several significant conceptual breakthroughs on the part of the learner.

Adjunct Online Tools

Cognitive support tools for deep learning on the Web are widely available. From Web text highlighting to page specific sticky notes, *adjunct online tools* abound, and new ones are released regularly. The number of modern tools to support deep Web learning dwarfs those available for traditional text or lecture-based environments. The unprecedented availability of these adjunct supportive aids also has significant cognitive load implications.

External memory aids like Clipmarks (http://www.clipmarks.com) make it effortless to save whole pages as well as small segments of pages (including images and video) in a personalized database. The information contained therein can be accessed by keyword, Boolean search, or chronologically, and increases the ease with which learners can criss-cross and revisit the information. This facilitates the recognition of interconnections, multiplicities, and differing contexts that are critical to the acquisition of flexible knowledge (Spiro & Jehng, 1990). At the same time, tools such as Google History and Trailfire (or even just concerted use of the tabs available in modern browsers for individual sessions) allow users to document and easily trace their paths through the web. While keeping extraneous cognitive load low relative to navigation (e.g., you can never really get lost), these services also have the potential to dramatically support the additional (germane) meta-cognitive activities that deep Web learning affords, by making explicit the paths of inquiry for later review, with little or no additional extraneous load.

Though not a specific tool, the functionality of *tagging* (assigning keywords to content of interest) also increases the potential benefits of deep Web learning. Most contemporary Web-based content management systems (e.g., Clipmarks), utilize this feature extensively. Tagging is a categorization activity that requires the assignment of meaning, a task that therefore represents germane cognitive load. Tagging information can represent an elaboration that fosters the encoding of long-term memories (Budiu, Pirolli, & Hong, 2007; van Merrienboer & Sweller, 2005). However, more important to learning in ill-structured domains, the application of multiple tags facilitates learner recognition of interconnections that may exist among the newly discovered information and previous information that has been similarly tagged. And, as Sinha (2005) noted, the practice of applying multiple tags to information may actually require a lower cognitive load than assigning information to a single category. She argued that upon encountering worthwhile information, multiple semantic concepts are typically activated in a learner. When forced to assign the information to one category, significant cognitive load is spent determining the *best* category, often resulting in what she called "post activation analysis paralysis" (para 16). However, the multiplicity of tagging allows learners to freedom to assign information to all related semantic concepts that are activated. She claims that it "taps into an existing cognitive process without adding much cognitive cost" (para 19).

There are also broader benefits to be accrued from tagging. For instance, Weinberger (2007) asserted that tagging *en masse*, combined with sophisticated data mining and search technologies, will facilitate better reconstructions of the implicit meaning of information on the Web. When available as part of the search process, this "meaning" will greatly focus searches for everyone, thus lowering any extraneous cognitive load related to filtering results.

The Question of Motivation

Recent developments in CLT have begun to integrate the importance of motivation, especially when considering "real-life," extended time tasks

(Pass, Tuovinen, van Merrienboer & Darabi, 2005; van Merrienboer & Sweller, 2005). And, while Astleitner and Wiesner (2004) raised concern for how a high density of motivational strategies explicitly designed for instructional settings may lead to increased cognitive load, we submit that motivation in deep Web learning is largely inherent, not an additional learning component that vies for space in working memory. Clearly, the specific cognitive load implications of motivation are just beginning to emerge. However, as Pass et al. (2005) noted "meaningful learning can only commence if training experience is coupled with the motivation to achieve well" (p. 26). More specifically, higher levels of learner motivation have the potential to increase the use of mental efforts that are germane to the learning outcomes.

Deep Web learning affords such increased motivation, and it was manifested in surprising ways in our recent study. Several times the subject noted his excitement about a particular path of inquiry, new and promising search phrases based on ideas from the current page, or a significant conceptual breakthrough. In a few cases a sort of learning *momentum* affected his motivations. Why? Although the exact processes are speculative at this point, we offer three ways deep Web learning appears to increase motivation, through attention, choice, and speed.

In Keller's (1987a; 1987b; 1999) Model of Motivation Design, he noted that *attention* and subsequent motivation could be gained through novel, surprising, incongruous, and uncertain events. We argue that novel, surprising, incongruous, and uncertain *ideas* discovered in the course of deep Web learning have a similarly enhancing effect on learner attention. And, since the Web interactions are not "designed" elements, they do not increase extraneous cognitive load, so that any increase in attention and effort likely serves to optimize germane cognitive load.

In addition, as Brophy has noted, much of what is known about optimal conditions for motivation cannot be easily applied in classrooms (in Gaedke & Shaughnessy, 2003). However, these very same ideas can and often do apply in deep Web learning, such as *learner control*. In typical classrooms, learner choice is minimized; however, considerable choice is afforded to Post-Gutenberg learners. They learn whenever and wherever they want. They choose what search phrases to use. They choose which results to visit. The assemblage of knowledge is personal in every way. The impact of this type of learning on personal attributions, expectations, and self-efficacy needs to be explored in more detail. However, we propose that once learners begin to feel empowered (which does not take long), they begin to *believe* that they can achieve their learning goals.

Finally, *speed* is essential to learner motivation on the Web. Everything happens fast. Resources are available in an instant. However, even more significant, our recent study of deep Web learning demonstrated a *quick transition* from early "fact-finding" to the *advanced stages of meaningful learning* that involved rapid interconnectedness and abstract/problem based thinking (Sheull, 1990). Accordingly, the subject indicated more excitement about these latter stages. The speed with which new information is available also impacts motivation. The learner can read reaction to yesterday's Senate hearings on climate change today, or in some cases can evaluate information in real-time. Access to *information this timely* empowers the learner, and may even make them feel like they know something others do not (including teachers).

Together, the impact of these motivational considerations on cognitive load needs further exploration, particularly for deep Web learning. However, we envision increased motivation, inherent in the learning process itself, providing substantial benefits to the process through increased germane mental efforts.

CONCLUSION

The chapter discusses how deep learning on the Web provides affordances that are well matched to the learning goals and requirements for flexible knowledge construction in ill-structured domains. In so doing, we have outlined a reconceptualization of germane cognitive load that is more appropriate for learning in ill-structured domains than that conceived by traditional Cognitive Load Theory. This new perspective makes it clear that mental efforts that are germane to learning in ill-structured domains are often extraneous in well-structured domains, and vice-versa. We have also discussed how specific aspects of deep Web learning in ill-structured domains help to optimize the ratio of germane cognitive load to extraneous cognitive load, including LICRA searching, serendipitous learning, resource evaluation, blog use, the availability of adjunct cognitive tools, tagging, and learner motivation.

Not everyone is prepared to take advantage of the benefits we have outlined. Nor do all domains of knowledge benefit from unfettered exploration in online multimedia environments. Additionally, cognitive load may be increased at first for novice Web learners. However, for ill-structured domains, deep Web learning holds great promise. The automatization of the basic skills required to successfully learn in depth on the Web happens quickly. The learner's skills improve with practice, and soon these skills are incorporated effortlessly within higher-level aspects of learning (e.g., LICRA searching and integrated resource evaluation), similar to how an advanced driver uses a steering wheel while navigating during rush hour. Expert drivers steer unconsciously while they attend to the landscape around them. So, too, will expert searchers direct themselves around the vast knowledge landscape of the Web without concerted effort. The automaticity of simple search skills leads to decreased extraneous cognitive load, freeing up resources for activities that are germane to flexible knowledge acquisition in ill-structured domains.

We are confident that the learning we describe above can become a large-scale reality. However, while we have concentrated on the potential benefits that deep Web learning will provide, obstacles to its success remain. For instance, the sheer quantity of resources available on the Web imposes a challenge. Learners may, even with the assistance of adjunct cognitive tools, drift away from relevant search results to information that is, in effect, extraneous to their efforts. In order to address these issues, we anticipate the need to develop loose meta-data structures similar to those employed in Cognitive Flexibility Hypertext systems (e.g., see Spiro, Collins & Ramchandran, 2007).

In addition, managing the *personal knowledge landscape* constructed by individuals immersed in deep Web learning may require support beyond what current adjunct online tools provide. Such support may take the form of more integrated tools capable of reducing the associated extraneous cognitive load. One such possibility would be the development of representative dynamic visual displays. We see the need for evolving network mind-maps, developed in an ongoing fashion with input from both the learner and the software in use. The information could be tagged by context so that the visual display highlights different information in different contexts, demonstrates the interconnectedness among ideas, facilitates revisitation, and provides significant meta-cognitive learning benefits. For example, this system could support three-dimensional mind-maps, each node mashed-up with the information from a Clipmarks-like database and relevant Google History details, and include visual representations of the interconnections that have formed.

FUTURE RESEARCH

To conclude, we offer the following: The Web will change the way that we think and learn, and these changes will be dramatic. It is inevitable. The timing of this revolution is fortuitous, since we are faced with increasingly complex and ill-structured educational and societal issues, both local and global in scale. Consider the difficulty we face assuming, as our forefathers did, that we have an "informed constituency" to support democracy. For example, climate change, health care, and globalization are "grand social challenges" that an informed electorate should understand to a much greater extent than is currently the case. These issues and others like them demonstrate ill-structuredness and they therefore require high levels of intrinsic cognitive load to understand. We believe that with concerted research efforts, ways for the Web to make learning about such issues cognitively manageable will result.

As a field, we need to be proactive in thinking about how to ensure that this happens. Our chapter is provided to encourage more researchers to examine this phenomenon in earnest. Myriad research opportunities and lines of inquiry exist and beg examination under both well-controlled and "real-life" conditions to determine the circumstances, knowledge domains, and learner characteristics for which new ways of learning will apply most broadly. What are the best ways to ensure that learners approach deep Web learning with an opening mindset? How will we best use tagging, LICRA searches and blogs to develop flexible knowledge appropriate to the challenges we face? Is the cognitive load for LICRA searching less than that for embedded links? If not, do the benefits outweigh the costs? Do triangulation methods of resource evaluation ensure an acceptable level of credibility? Do learners need to develop a certain level of expertise in the basic skills of deep Web learning in order for the motivational benefits we have offered to emerge? These questions, and many more, require the attention of researchers in order to better understand ongoing changes in the way we think and learn about critically important issues.

Chapter 8.17
General Strategy for Querying Web Sources in a Data Federation Environment

Aykut Firat
Northeastern University, USA

Lynn Wu

Stuart Madnick
Massachusetts Institute of Technology, USA

ABSTRACT

Modern database management systems are supporting the inclusion and querying of non-relational sources within a data federation environment via wrappers. Wrapper development for Web sources, however, is a convolution of code with extraction and query planning knowledge and becomes a daunting task. We use IBM DB2 federation engine to demonstrate the challenges of incorporating Web sources into a data federation. We, then, present a practical and general strategy for the inclusion and querying of Web sources without requiring any changes in the underlying data federation technology. This strategy separates the code and knowledge in wrapper development by introducing a general-purpose capabilities-aware mini query-planner and a data extraction engine. As a result, Web sources can be included in a data federation system faster, and maintained easier.

INTRODUCTION

Federated databases offer information integration on demand in dynamic environments, where data warehousing approaches are not feasible (Sheth & Larson, 1990; Geer, 2003). In modern relational database management systems, even non-relational sources can be included in a data federation via "wrappers" so that they can be queried as if they are part of a single large database (Somani, Choy, & Kleewein, 2002; Thiran, Hainaut, Houben, & Benslimane, 2006). Wrappers are mechanisms by which the federated server interacts with non-relational data sources by performing operations such as connecting to a data source and retrieving data from it iteratively.

Retrieving data from Web sources, however, is complicated because data is semistructured and Web sources may have requirements (e.g., they may require forms to be filled before returning data); thus general-purpose wrappers for arbitrary Web pages are not provided in data federation systems. Instead the user needs to implement a custom wrapper for each Web source by coding data extraction patterns and parts of the federated query planning protocol in a low-level programming language such as C. This convolution of code with the data extraction and planning knowledge turns wrapper development into a daunting task, results in code duplication, and slows down the data federation process.

Within the last decade or so, many research projects (Papakonstantinou, Gupta, & Haas, 1998; Levy, Rajaraman, & Ordille, 1996; Li & Chang, 2000; Zadorozhny, Bright, Vidal, Raschid, & Urhan, 2002; Li, 2003; Pentaris & Ioannidis, 2006) offered algorithmic solutions to "query planning with source restrictions." The goal of these studies was to offer an expressive language to specify source restrictions, and let the federated query planner come up with an optimal plan using this knowledge. These approaches do not need any cooperation from the individual data sources other than knowing about their limitations. Had they found their way into commercial systems, they would eliminate part of the code and knowledge convolution problem: the wrapper developer would only need to code the data extraction knowledge and not worry about the query planning aspects. Yet the separation of code and knowledge would still not be satisfactorily achieved in non-cooperative federated query planners. For this study, we have chosen to work with IBM DB2's cooperative federated query planner, which poses more challenges than the non-cooperative ones. Our focus is on improving the usability and maintenance aspects of the wrapper development process without requiring any changes in its underlying data federation technology. We do not offer yet another proposal to rewrite a state-of-the-art distributed query planner (Kossmann, 2000), or create an independent infrastructure for querying Internet data sources (Braumandl et al., 2001; Suciu, 2002), but provide a non-intrusive approach that works with what is available today with minimal effort.

We have tested our prototype implementation with numerous Web sites. A moderate user with no programming experience can include a typical Web site into a data federation in less than an hour. The process often takes much longer when the existing procedural coding approach is used by an experienced programmer. Furthermore, explaining, learning, and tutoring wrapper development becomes much easier, as the task changes from writing and debugging a *program* to specifying and debugging *knowledge*.

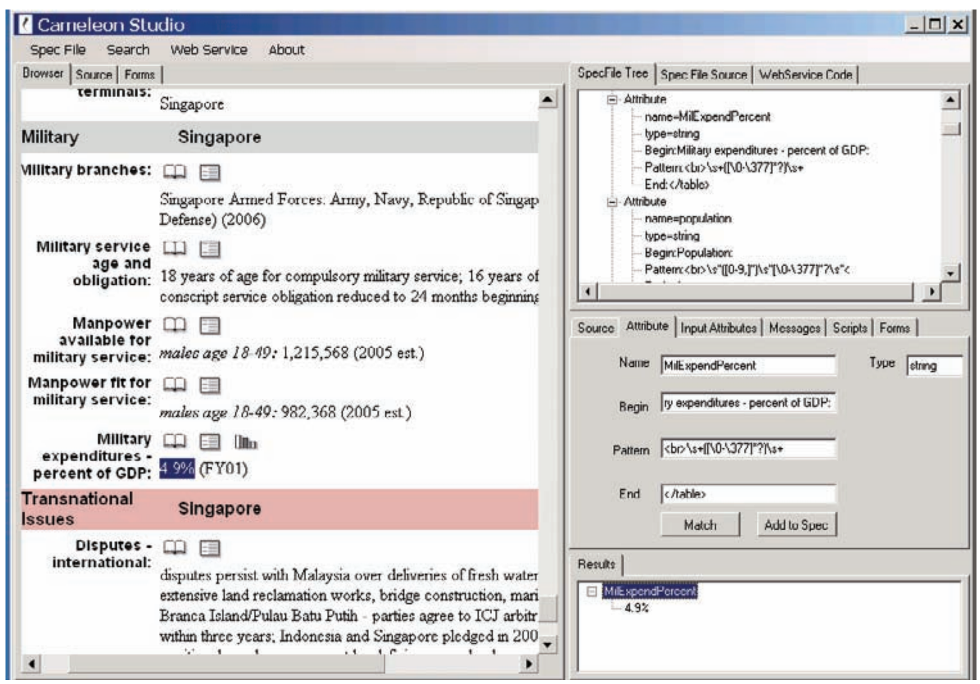
In the rest of this paper, we start with a motivational example that illustrates the need for data federation involving Web sources. We then provide some background on data federation with non-relational data sources and describe the current architectural difficulties of incorporating a Web source. Next, we describe our approach to wrapper development, and the algorithms used to perform planning and optimization for Web sources with capability restrictions. We end with an overview of related work and future research issues.

MOTIVATIONAL EXAMPLE

Consider, first, finding the *military expenditure per capita* of countries in the world using the CIA world fact book Web site. This information is scattered inside the world fact book (see Figure 1), and first needs to be located and extracted.

Figure 1. Available data in CIA World Fact Book site

Figure 2. CIA World Fact Book site is visually wrapped with Cameleon# Wrapper Engine



By using the Web wrapper, Cameleon# (Firat, Madnick, Yahaya, Kuan, & Bressan, 2005; Firat, Madnick, & Siegel, 2000) and its accompanied visual helper, Cameleon# Studio, we can wrap the CIA world fact book site using simple regular expressions and treat it as a very simple relational table as illustrated in Figures 2 and 3.

The Cameleon# wrapper engine's main functionality is, however, extraction and thus is only able to answer SQL queries involving a single source, with required inputs bound to a single set of values at a time. For that reason, we decided to use the powerful query planning, optimizing, and execution capabilities of a commercial data federation engine to handle more complex query situations. Using the extended architecture to be described later on, we define a nickname for our Web source in DB2 as shown below:

```
CREATE NICKNAME CIA (
country char(20),
population dec(10,1),
```

GDP dec(10, 2),
GDP_unit char(20),
MilExpendPercent dec(9,4) for server Cameleon#_server
options(SERVER_NAME 'http://interchange.mit.edu/Cameleon_sharp/camserv.aspx?',
PREDICATES 'country')

The options in the above description indicate the location of Cameleon# information extraction server, and the required input column *country*. We are then able to treat the CIA fact book like a relational table and issue the following query using DB2:

```
Q1: SELECT country, population, GDP,
    gdp _ unit, MilExpendPercent
       FROM cia
       WHERE country IN
   ("Singapore", "Israel", "United States",
"United Kingdom", "Malaysia")
```

(see Table 1)

Since we want to calculate the *military expenditure per capita*, we need to perform the appropriate calculation with a mathematical expression. In addition, we must perform unit conversions (e.g., adjust for the fact that some GDP values are in billions and some in trillions) with the auxiliary database table scalefactor:

TEXT	SCALE
Billion	1000000000
Trillion	1000000000000

This is achieved by joining the non-relational CIA Web source with the relational scalefactor table using the following query:

```
Q2: SELECT country, (MilExpendPercent * GDP
       * scalefactor.scale / population)
AS MilExpPerCapita
   FROM cia, scalefactor
   WHERE scalefactor.text=cia.gdp_unit AND
country IN
("Singapore", "Israel", "United States", "United
Kingdom", "Malaysia")
```

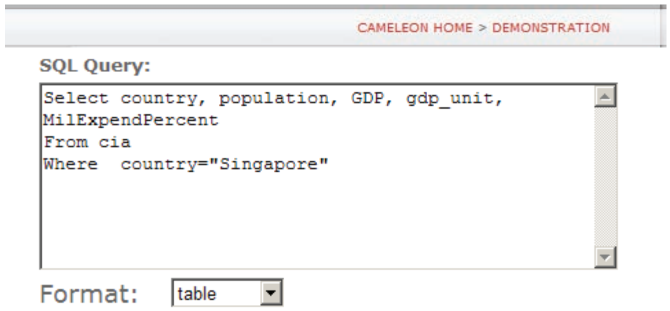
COUNTRY	MilExpPerCapita
Singapore	1379.85
Israel	1901.93
United States	1674.64
United Kingdom	716.72
Malaysia	238.91

Finally, we would like to obtain the *military expenditure per soldier* by creating another NICKNAME for a Wikipedia Web source that has the sizes of armed forces and formulating a federated query joining multiple Web sources, as shown in Figure 4.

Table 1.

COUNTRY	POPULATION	GDP	GDP_UNIT	MILEXPEND-PERCENT
Singapore	4492150	126.5	billion	4.90
Israel	6352117	156.9	billion	7.70
United States	298444215	12.31	trillion	4.06
United Kingdom	60609153	1.81	trillion	2.40
Malaysia	24385858	287	billion	2.03

Figure 3. Simple SQL Query against the wrapped CIA World Fact Book



country	population	gdp	gdp_unit	milexpendpercent
Singapore	4492150	126.5	billion	4.90

Figure 4. Available data in Wikipedia

11.		Egypt	0450	0254

```
CREATE NICKNAME ARMFORCES (
country char(15),
armed_forces integer)
for server Cameleon#_server
options(SERVER_NAME
'http://interchange.mit.edu/Cameleon#_sharp
/camserv.aspx?',
PREDICATES 'country')
```

```
Q3: SELECT cia.country, armed_forces,
      (MilExpendPercent*GDP*scalefactor.uni
      t)/ (armed_forces*1000) AS
      milpersoldier
FROM cia, armforces, scalefactor
WHERE cia.country IN ('Singapore',
'Israel',
```

COUNTRY	ARMED_FORCES	MILPERSOLDIER
Singapore	60	103308.33
Israel	168	71912.50
United States	1426	350481.07
United Kingdom	190	228631.58
Malaysia	110	52964.54

As this simple example shows, querying Web sources using a data federation offers many operational benefits. One can take advantage of the relational database technology in processing semistructured Web data. For example, Web sources can be joined with each other and with other sources, calculations and set operations can be performed, and queries can be optimized. Currently, however, even setting up this motivational example is extremely difficult, if not impossible using one of the data federation engines. The most direct solution offered by DB2 requires coding a custom wrapper for each Web source, but even then those Web sources cannot be joined with each other on the required input attributes (IBM, 2006).

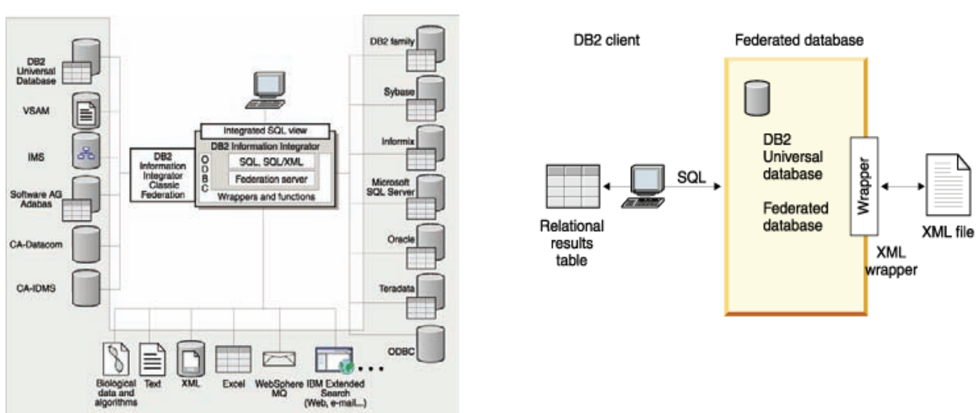
We designed and implemented a new architecture that drastically accelerates the inclusion and querying of Web sources in a data federation. The motivational example, for instance, can be set up in less than an hour without any low-level programming. Users only need to locate and specify the information they want to use on the Web with Cameleon# Studio--a point and click helper tool--and define the Web sources with data definition statements similar to classical "CREATE TABLE" statements. Before explaining the details of our extended architecture, we provide background on the typical operation of data federation systems by using DB2 and its Request-Reply-Compensate protocol as an example.

QUERYING NON-RELATIONAL SOURCES IN A DATA FEDERATION

The goal of a data federation system is to allow clients to access diverse and distributed data sources, regardless of location, format, or access language, from a single interface. While data federation may have a slower access performance compared to data consolidation (as in data warehousing), it has the benefits of (i) *reduced implementation and maintenance costs*, (ii) *access to current data from the source of record*, and (iii) *combining traditional data with mixed format data* (IBM, 2006; Haas, Lin, & Roth, 2002).

As shown in Figure 5, a data federation system uses wrappers to access non-relational data sources such as flat files, XML pages, and Web services. After the user submits a query, the federated server collaborates with the wrapper for each data source to generate an optimized access plan for the query and then evaluates it. Such a plan might call for parts of the query to be processed by the wrappers, by the federated server, or partly by the wrappers and partly by the federated server. The federated server chooses among the plans primarily on the basis of cost.

Figure 5. IBM DB2 data federation architecture [Adopted from (DB2 Information Center 2006)]

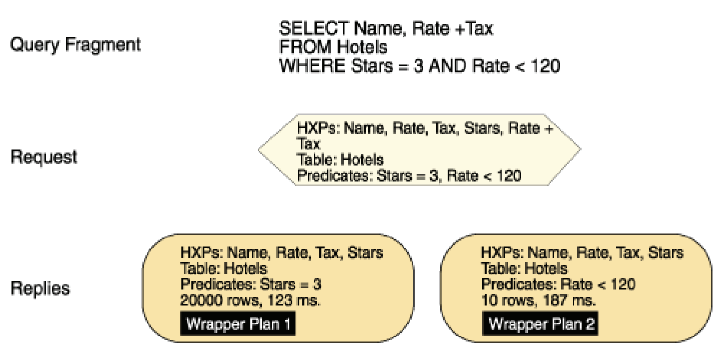


Upon receiving the *request*, the wrapper indicates which sub-pieces of the query fragment it can evaluate, and puts this information in the *reply* to the request. Request properties such as cost, cardinality and ordering properties can also be included. For a typical request, a wrapper could return zero or more reply objects. Each reply represents a different accepted fragment. By the end of query planning, the federated server will weigh all the cost estimations and determine a query execution plan incorporating some set of the accepted fragments offered up by the wrapper in response to requests. During query execution, the federated server will ask the wrapper to execute these query fragments. The federated server can also *compensate* for any query fragments that have not been accepted. Examples of this include a complex predicate or sorting that is beyond the capability of the data source in question. This protocol is therefore called a *request-reply-compensate protocol* in IBM DB2.

Consider Figure 6 as an example. The query fragment (`SELECT Name, Rate + Tax FROM Hotels WHERE Stars=3 AND Rate < 120`) is passed to the wrapper as a request by indicating the head expressions (HXPs), table name, and the predicates. In this case, we assume that the wrapper cannot handle the complete request as it cannot do the `Rate + Tax` calculation and it cannot do two predicates at a time, so replies with two separate parts, which when combined in the federated server answers the original query.

The request-reply-compensate protocol offers a generic framework allowing the federated server to communicate with non-relational data sources through a black box wrapper. Among the built in wrappers that comes with IBM DB2, there are two that are particularly relevant to querying Web sources: XML and Web services wrappers. These wrappers can be used if Web sources can be turned into XML format, or Web services. Neither of these, however, satisfies our desire to include an arbitrary Web source in a data federation and query them without artificial restrictions. The XML wrapper, for instance, does not have the concept of a required input attribute: the XML page should be accessible with a fixed address. Many Web sources are dynamically generated based on input attributes, which precludes the use of XML wrapper as it is. The Web services wrapper, on the other hand, has artificial query restrictions such as "*no IN or OR predicates are allowed for input columns*" (IBM, 2006). For instance, even our simplest query `Q1` cannot be handled by the Web services wrapper assuming our Web source was somehow turned into a Web service.

Figure 6. Request-Reply-Compensate protocol example [Adopted from (DB2 Information Center 2006)]

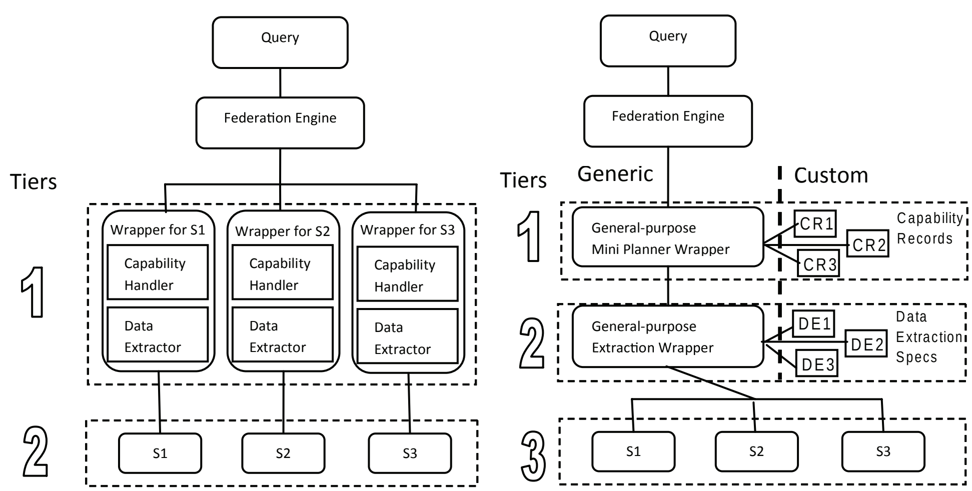


THREE-TIER ARCHITECTURE FOR QUERYING WEB SOURCES IN A DATA FEDERATION

The solution we offer for the inclusion and querying of Web sources in a data federation involves extending the existing two-tier custom wrapper architecture into a three-tier architecture while separating the generic and custom aspects of wrapper development as shown in Figure 7. This new architecture separates code and knowledge, minimizes redundancy, and complements the central query planner when incorporating web sources in a data federation by following the wrapper development protocol specified in DB2 Information Integrator Wrapper Developer's Guide (IBM, 2004).

In the first tier of our solution we have a general-purpose mini planner-wrapper responsible for planning queries involving Web sources. We call it a mini-planner because Web sources have characteristics that limit the query planning space; therefore we do not have to deal with the complexity of a traditional query planner. Our mini planner, in most cases, only needs to handle query planning for a single Web source, leaving complex planning involving multiple sources to the federated server. The mini planner can run Web source queries in parallel, and order them intelligently when they are joined, while respecting their capabilities. Web source capabilities are expressed using simple capability records, which indicate the required input attributes, and whether input attributes can be bound to more than one value at a time. For example, the capability record [b(1), f, f, f, f] for the CIA nickname means that the first attribute *country* needs to be bound with one value at a time (b(1)), and the rest of the attributes must be free (f). In general b(N) indicates that the attribute can be bound with up to N values; "f" indicates that the attribute must be free; and "?" indicates that the attribute can be either bound or free. These capability records are implemented for each source using the nickname definition, right after the predicate keyword. The second-tier is a general-purpose data extraction engine responsible for retrieving data from a Web source and presenting it in the format expected by the data federation engine. For this task, any capable general-purpose data extraction engine

Figure 7. Comparison of Architectures. The extended architecture separates data extraction and capability handling functionalities. Furthermore the primary wrapper is responsible for planning queries posed against web sources with capability restrictions



can be used. We used the data extraction engine, Cameleon#, which uses declarative rules based on regular expressions to extract data from Web pages. Cameleon# Studio can be used to help generate the necessary specification file. An example specification file is shown in Figure 8.

The second-tier extraction wrapper accepts these specification files as input to extract data from any Web source without any procedural coding. Next, we provide the details of the mini query planner for Web sources with capability restrictions.

MINI QUERY PLANNER FOR WEB SOURCES

The mini query planner creates a plan that can efficiently retrieve remote data while satisfying query restrictions. Generally, a query planning engine needs to decompose the original query into component subqueries (CSQ), such that each CSQ can be answered using a single data source (Alatovic, 2001; Fynn, 1997). Our mini query planning engine does not need to perform the decomposition since the federated database engine already divides the original query into CSQs, known as requests, where each request can be processed by a single data source. In addition to query decomposition, a query planning engine also needs to maintain the CSQ execution order. Typically, independent CSQs are executed first, followed by dependent CSQs that can be answered using prior results. Thus, detecting the dependencies among the CSQs is crucial to successful planning. Our query planning engine uses both the federated engine and capability records to analyze CSQ dependencies. When the CSQ dependency can be determined using query semantics, our query planning engine uses the federated database engine. When a CSQ does not meet all the capability restrictions of a source, however, the query planning engine will determine if information from other parts of the query can be used to satisfy the capability restrictions. If the restrictions can be satisfied, the CSQ will be modified with the required information so that it can be answered by the native data source.

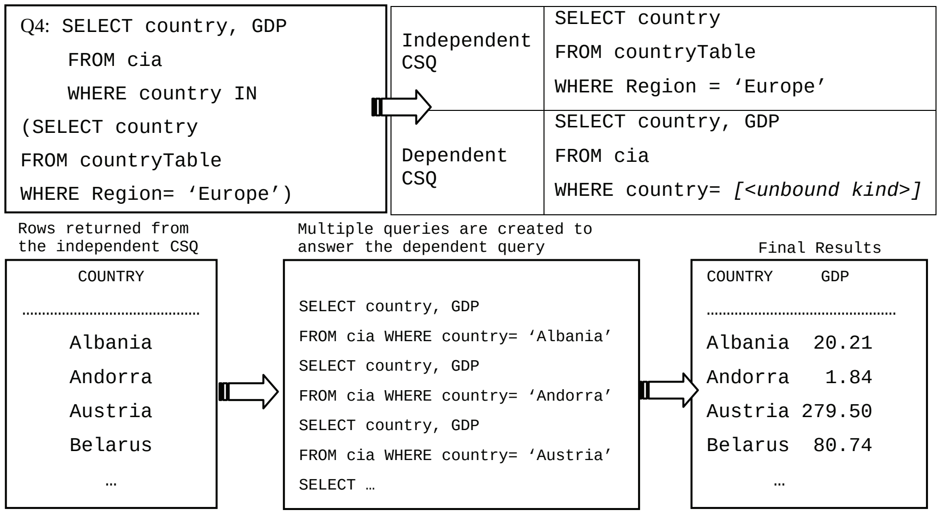
The simplest case for a query execution plan (QEP) is when all CSQs meet the capability restrictions imposed by their native data sources, and they can be executed independently and in parallel. In this case, the federated engine simply decomposes the original query into CSQs and sends them to the native sources through wrappers. After receiving all processed row sets from the native sources, the federated engine aggregates the data and returns the final result.

When a CSQ cannot be executed by itself, however, it is necessary to determine if the CSQ can still be processed using results from other CSQs. Two procedures are used to determine the dependencies: the first method relies on detecting dependencies using query semantics; the second method employs the capability records to meet any unsatisfied restrictions using information from other processed CSQs. The next two sections describe in detail how the two procedures work and how they compensate for each other.

Dependencies Detected via Query Semantics

In Figure 9, we show an example dependency between CSQs that can be detected using the query semantics. In this example, the original query is decomposed into an inner-select CSQ, which can be executed independently, and an outer-select CSQ, which depends on the data returned by the inner-select CSQ. The federated engine facilitates the detection of this dependency by tagging country attribute with a type called *"unbound kind"* to signal to the wrapper that the binding values would be available after the inner-select CSQ is executed. Once the result from the inner-select CSQ is returned, the wrapper needs to create a new set of CSQs by replacing the *"unbound kind"* tag in the original CSQ with the returned value(s). In this example, as illustrated in Figure 9, since country names are returned from the inner-select CSQ; (e.g., Albania, Andorra, Austria, Belarus, etc.), new CSQs are formed after binding each country name to the country attribute. The wrapper then needs to send this new set of CSQs to the native data source. Once the native source processes the CSQs, the wrapper needs to assemble the results and return them to the federation engine. In this example, the wrapper sends the queries to the CIA Web source, retrieves the GDP values and returns them to the federated engine.

Figure 9. An example query dependency that can be detected by query semantics



Dependencies Implied by Capability Restrictions

Some CSQ dependencies may be not be detected via query semantics, but are implied by capability restrictions. Consider for example query Q5, which asks for the GDP and armed-force size of countries that are ranked in the top 10 both in terms of highest GDP and largest armed-force size. Like in the previous example, *countryTable* is a relational source that has the list of countries and their regions.

```
Q5: SELECT cia.country, armed_forces, GDP
FROM countryTable,
(SELECT GDP
 FROM cia
 ORDER BY GDP DESC FETCH FIRST 10 ROWS ONLY) cia,
(SELECT armed_forces
 FROM armforces
 ORDER BY armed_forces DESC FETCH FIRST 10 ROWS ONLY) armforces
WHERE cia.country = countryTable.country AND
armforces.country = countryTable.country
```

To process this query, the query planning engine needs to invoke the countryTable relation to retrieve the list of all countries, and then pass them to the cia and armed_forces relations to obtain the requested data. In order to answer this query, however, the federated engine creates the following two CSQs on Web sources:

```
CSQ1: SELECT GDP
 FROM cia

CSQ2: SELECT armed_forces
 FROM armforces
```

Since none of the CSQs has unbound parameters, the federated engine assumes that they can be executed independently by using the native data sources. Both Web sources, however, require that *country* must be bound before they can return any results. Thus, we cannot produce an answer to the query by only using query semantics. If we consider the capability information, however, it is possible to process both CSQs by finding the missing information from other parts of the query. Using the join conditions “cia.country = countryTable.country” and “armforces.country = countryTable.country” we can rewrite CSQ1 and CSQ2 into CSQ3 and CSQ4 by providing the values for the country attribute from the countryTable relation:

```
CSQ3:SELECT GDP
  FROM cia
  WHERE country IN
  (SELECT country FROM coun-
tryTable)
```

```
CSQ4:SELECT armed_forces
  FROM armforces
  WHERE country IN
  (SELECT country FROM coun-
tryTable)
```

With this added condition, CSQ3 and CSQ4 satisfy the capability restrictions and thus can be processed by the native sources. Although CSQ3 depends on the result from countryTable, this dependency can now be resolved via query semantics with the help of the federation engine as in Figure 10.

The query execution plan (QEP) algorithm, which uses capability records to process CSQs, is presented in Figure 11. The algorithm is based on finding independently executable CSQs in the query and processing them before any dependent CSQs. In most cases, the CSQs that cannot be executed independently lack at least one binding restriction. Once such a CSQ is detected, the algorithm determines if the CSQ can still be executed by searching for the missing binding from other CSQs. If the algorithm finds the missing binding, it is incorporated into the CSQ so that it can be processed by the native source.

Figure 10. An example query dependency implied by capability restrictions

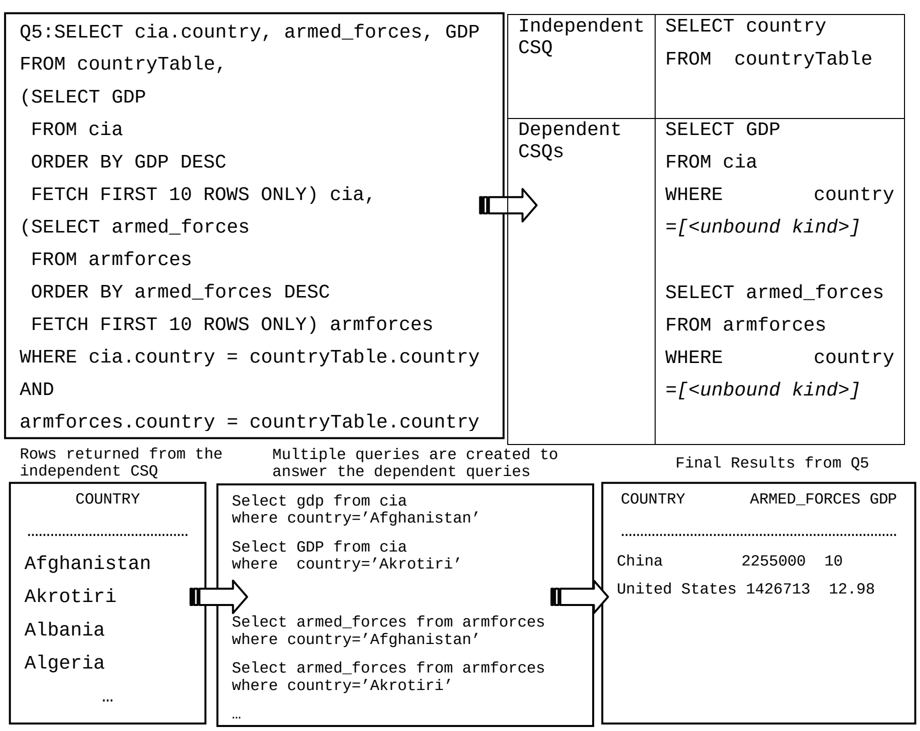


Figure 11. QEP generation algorithm supporting binding query restrictions

```
Input: Single Query q
Output: Query Execution Plan (QEP)

QEP Generation Algorithm:
1.   initialize set S to an empty set
2.   for all CSQs c in S
3.        if c is independently executable
4.        add c to set S
5.        add entry 0:c to QEP
6.   repeat until no more CSQs are added to S
7.        for all CSQs c outside of S
8.             if CSQ c can be executed using bindings from CSQs in S
9.               add an entry for c to QEP including all join bindings of c
10.              add CSQ c to set S
11.   if S does not contain all CSQs in a query
12.        throw exception "query cannot be executed"
13. return QEP
```

There are two non-trivial steps in this algorithm: a) determining if a CSQ can be independently executed (step 3), and b) deciding whether a CSQ can be processed using join bindings from a set of executed CSQs (step 8). The details of these two steps are illustrated in the following sections.

Determining Independently Executable CSQs

Figure 12 shows the algorithm for determining whether a CSQ is independently executable. The algorithm uses the capability restrictions to detect any missing binding in the CSQ, and if they exist, the algorithm determines if these binding conditions can still be satisfied.

Determining Whether a CSQ is Executable Given a set of Executed CSQs

The algorithm for determining whether a CSQ is executable, given a set of CSQs that have already been executed, is depicted in Figure 13. Consider the earlier example in Figure 10 once more. Although the cia and armforces CSQs cannot be executed independently, they can still be processed by finding the missing binding through the use of join conditions in the query. This algorithm detects this class of CSQs that are missing bindings, but can still be executed using information made available through executing other parts of the query. For the specific example of Figure 10, upon finding the attribute country to be unbound, the

Figure 12. Algorithm for determining whether a CSQ is independently executable

```
Independently Executable CSQ:
1. for all binding specifiers bs of c's underlying relation r
2.     for all attribute specifiers as of bs
3.     if as is of type bound and there is no binding in CSQ c
for corresponding attribute
4.                 continue 1
5.            else
6.                 continue 2
7.      end for
8.   return true
9.   end for
```

Figure 13. Algorithm for determining whether a CSQ is executable given a set of executed CSQs

```
Input:    set of executed CSQs S, new CSQ n
Output:  if n cannot be executed given join bindings from CSQs in S
                 returns null
             else
                  returns list of join bindings for CSQ n
CSQ Executable:
1.   for all binding specifiers bs of CSQ n
2.        initialize list of join bindings to an empty list jbl
3.        for all attribute specifiers as of bs
4.             if as is of type bound and CSQ n does not contain binding
                  for attribute matching as
5.                  if there is a join binding jb from n's attribute
                        matching as to one of CSQs in S
6.                  add jb to jbl
7.                  continue 3
8.             else
9.                  continue 1
10.        return jbl
11. return null
```

algorithm discovers a joint binding, countryTable.country=cia.country, that can provide the missing values to the attribute *country*. After modifying the cia CSQ with the new joint binding, the cia CSQ can be executed. Similarly, the binding for armforces CSQ is discovered from the countryTable.country=armforces.country predicate; the CSQ is modified and executed.

Handling Key-at-a-Time Query Restriction

Many Web sources require a single key value to be provided at a time. Consider for example the query Q1 again. (Cia web source has b(1) – one binding at a time – restriction on the attribute country):

```
Q1: SELECT country, population, GDP,
gdp _ unit, MilExpendPercent
    FROM cia
    WHERE country IN
```
("Singapore", "Israel", "United States", "United Kingdom", "Malaysia")

In order to answer this query, the mini-planner needs to change the query into a union of four one-key-at-a-time queries, and perform the union operations locally in parallel. In general, Web sources may have b(N) – N binding at a time – restriction. The short algorithm, shown in Figure 14, handles the general case by recursively rewriting the original query into subqueries. Finally, the algorithm returns the result by performing the union operator on the results of all the subqueries.

Cost Statistics Generation

Cost statistics are especially important for federated queries (Kache, Han, Markl, Raman, & Ewen, 2006). The mini planner wrapper can also return cost statistics for Web sources to the federated engine to aid in query optimization. These cost statistics, as described in DB2 Information Center, are:

1. The cardinality of a nickname. This is defined as the number of rows contained in the nickname (default 1000 rows).
2. The setup cost for a nickname. Setup cost represents the typical time, in milliseconds, that it takes a wrapper to get a query fragment ready to submit to the remote source (default 25 milliseconds).
3. The submission cost for a nickname. Submission cost represents the typical time, in milliseconds, that it takes a wrapper to submit a query fragment to the remote source (default 2000 milliseconds).
4. The advance cost for a nickname. This is the typical time, in milliseconds, that it takes to fetch a single row for the nickname (default 50 milliseconds).

Among these cost statistics, the set up and submission cost can be easily figured out, but the cardinality and the advance cost for a nickname are not easy to calculate for dynamic Web sources. We can, however, estimate the cardinality and advance cost for a nickname by keeping time statistics and cardinality information of previously executed CSQs on the same underlying relation. The estimation process can be initiated by starting with a conservative default time estimate and then improving on it using time statistics on recently executed CSQs on the same underlying relation.

RELATED WORK AND DISCUSSION

Our general strategy for querying Web sources in a data federation system fundamentally differs from other studies (see Florescu, Levy, & Mendelzon, 1998, for a review) in the same area for two reasons:

1. We clearly separate knowledge from code in wrapper development, and improve wrapper development speed and ease of maintenance.
2. We do not assume that we have the liberty to recode the existing federated database systems; thus we focus on improving the process of including and querying Web

sources in cooperation with the existing data federation planners.

The majority of the studies in the area are concerned with query planning under source capability restrictions, and we find two types of approaches in the existing literature: 1) the black-box approach of pushing the capability handling to the wrapper level, and 2) the central planning approach by using a complex declarative language to describe capability restrictions. The IBM DB2 follows the first approach: handling capability restrictions is pushed down to the wrapper layer and it relies on Request-Reply-Compensate protocol to communicate with the wrappers. Although this is a generic framework to incorporate many different sources, coding a different wrapper every time for a Web site with different capability restrictions can be extremely wasteful and error-prone, since most of the code between these wrappers will be common.

There are projects that follow the second approach by describing capability restrictions with a declarative yet complex language. Examples of research projects, which more or less take this route, are Garlic Project at IBM (Roth & Schwarz, 1997; Papakonstantinou, Gupta, & Hass, 1998; Hass, Kossman, Wimmers, & Yang, 1997), TSIMMIS Project at Stanford (Chawathe, Garcia-Molina, Hammer, Ireland, Papakonstantinou, Ullman, & Widom, 1994), Information Manifold (Levy, Rajaraman, & Ordille, 1996), and DISCO (Tomasic, Raschid, & Valduriez, 1998). While this approach is more generic, it has not found its way into existing data federation technologies – perhaps due to its complexity.

The approach we take is a hybrid of these two. As in the black box approach, we push the capability handling to the wrapper level, and like the central planning approach we use declarative capability records. Yet these capability records are designed only to handle Web source access limitations and are not as general as the approaches found in the literature. This restriction simplifies the development of the query planner. Furthermore, our mini query planner creates query plans in cooperation with the central federated query planner, and thus differs from the central planning approach, which does not cooperate with the individual sources.

Another major difference we present is the clear separation of extraction and planning knowledge from the code. This is summarized in Table 2. The wrapper developer only deals with the task of specifying extraction and capability knowledge, and is not involved with low level coding as in other approaches.

Do not Web Services Solve the Problem?

It may be mistakenly thought that the solution offered here would not be needed if the Web sources were Web services returning XML. In fact, we are able to create virtual Web services from any semistructured Web source by using a version of the Cameleon# Web wrapping tool. The capability restrictions, however, are still valid problems for Web services, which often require input attributes before returning any results (Petropoulos, Deutsch, Papakonstantinou, & Katsis, 2007). There is an extra benefit of using

Table 2. Code and knowledge separation in Web wrapper development

	Extraction knowledge	Planning knowledge
Cooperative Planning Approach	Embedded in code	Embedded in code
Central Planning Approach	Embedded in code	Declarative
Our approach	Declarative	Declarative

Web services, as the capability restrictions could be automatically deduced from the Web service description language (WSDL) document instead of declaring them in the nickname statements. All the query dependency issues for arbitrary Web sources, however, equally apply to Web services as well. In fact, the built-in IBM wrapper for Web services prohibits the formulation of queries where dependencies create problems. Our solution is more general and can be used for Web services without artificial restrictions.

CONCLUSION

The Web is undoubtedly the largest and most diverse repository of data; unfortunately it was not designed to offer the capabilities of traditional database management systems. Modern databases promise to include Web sources in a data federation via "wrappers" so that they can be queried as if they are part of a single large database. There are still, however, significant hurdles to fulfilling this promise. With this study we introduced an improved way of dealing with Web source wrappers in federated database applications. With this new general strategy not only do we accelerate the inclusion of Web sources in federated databases, but also we are able to eliminate unnecessary query restrictions. Our contribution is not only at a conceptual level, but also has been implemented using IBM's commercial database engine DB2. Most importantly, all of this has been achieved via extensions allowed by the federation engine, and without requiring any implementation changes in the existing data federation technology.

ABSTRACT

Web technologies are being even more adopted for the development of public and private applications, due to the many intrinsic advantages. Due to this diffusion, estimating the effort required to develop Web applications represents an emerging issue in the field of Web engineering since it can deeply affect the competitiveness of a software company. To this aim, in the last years, several estimation techniques have been proposed. Moreover, many empirical studies have been carried out so far to assess their effectiveness in predicting Web application development effort. In the chapter, we report on and discuss the results of the most significant empirical studies undertaken in this field.

INTRODUCTION

The availability of powerful server-side, Web-oriented component technologies, such as J2EE, ASP.NET, and so forth, has led to profound changes in the scenario of software systems, allowing developers to create "Web applications," that is, highly-dynamic systems able to deliver a complex amount of functionalities, while running in a Web browser. The approach provides many advantages. In particular, it permits deployment of applications without caring of the client platform, it fully exploits the MVC architecture, and it allows different applications to easily interoperate, by using standard communication protocols and languages, such as XML. As a result, Web applications are becoming an essential support for the every-day activities of both public and private organizations. For instance, to date, most intranet applications, such as document management systems, workflow, and business organization, and B2B solutions are developed with this approach.

On the other hand, the development of these applications has introduced a set of unique features and characteristics, quite different from traditional software construction (Deshpande, 2002; Ginige & Murugesan, 2001). The main issues can be summarized as follows: the requirements are instable, their development is usually characterized by pressure time and compressed schedule; the employed technologies rapidly changes (technology instability), they are usually developed by a small team including young developers, with different backgrounds and knowledge, compared to a traditional software development team. So, a lot of research is needed to provide software engineers with tools and methodologies able to ensure a cost-effective development of this kind of systems. In particular, the traditional approaches for software cost estimation need to be adequately modified to take into account the specific characteristics of these applications. To this aim, currently, many researchers are addressing the crucial problem of estimating the effort required to develop Web applications. Indeed, development effort, meant as the work carried out by software engineers, is the dominant project cost, being also the most difficult to estimate and control, with significant effects on the overall costs. So, effort estimation is a critical activity for planning and monitoring software project development and for delivering the product on time and within budget. Significant over or under-estimates can be very expensive and deleterious for a company. Thus, it is paramount for the competitiveness of a company to be able to effectively predict in advance the effort required to develop a Web-based project (Baresi, Morasca, & Paolini, 2003; Costagliola, Di Martino, Ferrucci, Gravino, Tortora, & Vitiello, 2006a; Mendes, Counsell, & Mosley, 2003b; Reifer, 2000; Ruhe, Jeffery, & Wieczorek, 2003b), and Web effort estimation is an important topic in the field of Web engineering. In this context, special attention is devoted to identifying suitable tools and approaches and to proving by empirical studies that the proposals can be effectively and affordably used in the industrial context.

Goal of the Chapter

The objective of this chapter is to report on the most significant empirical studies undertaken so far and aimed at assessing the effectiveness of measures and techniques for estimating Web application development effort.

BACKGROUND

In the literature, a lot of different methods to estimate software development effort have been proposed. A widely accepted taxonomy of estimation methods classified them in *Non-Model Based* and *Model Methods* (Briand & Wieczorek, 2002).

While *Non-Model Based Methods* mainly take into account expert judgments (thus with highly subjective factors), *Model Based Methods* involve the application of some algorithms to a number of inputs to produce an effort estimation. The inputs for these algorithms are the factors that heavily influence the resulting development effort of a software project. Among these, *Software Size* is accepted as a key cost driver, since it deeply affects total development effort, and thus total project cost (Bohem et al., 2000). Consequently, being able to obtain an early *size measure* for a project can provide a significant estimation of the overall development cost.

In the context of Software Engineering, widely employed *Model Based* estimation methods are Linear Regression (LR), Case-Based Reasoning (CBR), and Regression Tree (RT) (see, for example, Briand, El-Emam, Surmann, Wiekzorek, & Maxwell, 1999b; Briand, El-Emam, & Wiekzorek, 2000; Shepperd & Schofield, 2000).

These approaches use data from past projects, characterized by attributes that are related to effort (e.g., the size), and the actual effort to develop the projects, to estimate effort for a new project under development. In the last years, many researchers and practitioners tried to apply these methods to Web applications. In particular, in the literature there are several works that address the problem of estimating the effort required to develop Web applications (Baresi et al., 2003; Costagliola et al., 2006a, 2006b; Mendes, Counsell, & Mosley, 2002a, 2003a, 2003b; Mendes, Counsell, Mosley, Triggs, & Watson, 2002, 2003; Reifer, 2000; Ruhe, Jeffery, & Wieczorek, 2003a) by identifying measures related to effort and validating them by empirical studies. Indeed, it is largely acknowledged that a software measure and/or estimation method or technique can be acceptable and effectively usable only if it has been validated through several empirical studies proving its usefulness (Basili, Briand, & Melo, 1996; Basili, Shull, & Lanubile, 1999; Briand et al., 1999b; Genero & Piattini, 2001; Mendes, Counsell, & Mosley, 2003b; Myrtveit, Shepperd, & Stensrud, 2005; Schneidewind, 1992).

A crucial aspect in performing empirical studies concerns the availability of a data set of past projects. Indeed, in order to build a model to estimate the effort of a new project, *Model Based Methods* exploit information of past projects on the actual development effort and on the factors that can influence the effort (e.g., the software size). Recently, some researchers have addressed the issue to understand whether a cross-company data set (i.e., a data set containing project data from several software companies) can provide estimates for the new projects comparable to the one obtained from single-company data sets (i.e., data sets containing project data from a single company). Several empirical studies have addressed this issue (see, for example, Briand, El-Eman, Maxwell, Surmann, & Wieczorek, 1999; Jeffery, Ruhe, & Wieczorek, 2000, 2001; Lefley & Shepperd, 2003; Mendes, Lokan, Harrison, & Triggs, 2005; Ruhe & Wieczorek, 2002).

Estimation Techniques

Linear Regression (LR) is a statistical technique that explores the relationship between a dependent variable and one or more independent variables, providing a prediction model described by an equation$y = b_1x_1 + b_2x_2 + ... + b_nx_n + c$where y is the dependent variable, $x_1, x_2, ..., x_n$ are the independent variables, for i=1,..,n, b_i is the coefficient that represents the amount the variable y changes when the variables x changes 1 unit, and c is the intercept (Montgomery, Peck, & Vining, 2001).

In effort estimation, LR is usually exploited to obtain linear regression models that use the variable representing the effort as dependent and the variables denoting the employed size measures (e.g., number of Web pages, number of *Web Objects*, number of *COSMIC-FFP*, etc.) as independent. Once the prediction model has been constructed (i.e., an instance of the previous equation), the effort estimation for a new project can be obtained by substituting in this equation the project size, expressed in terms of the employed measure.

The idea behind the use of the Case-Based Reasoning (CBR) technique is to predict the effort of a new project by considering data on similar projects previously developed. In particular, the completed projects are characterized in terms of a set of *p* features, forming the *case base*. The new project is also characterized in terms of the same *p* attributes and it is referred as the *target case*. Then, the similarity between the target case and the other cases in the *p*-dimensional feature space is measured, and the most similar cases (or projects) are used, possibly with adaptations to obtain a prediction for the target case (Aamodt & Plaza, 1994; Myrtveit & Stensrud, 1999; Shepperd & Schofield, 2000). To apply the CBR technique, a Measurer has to select: the relevant project features, the appropriate similarity function, the number of analogies to select the similar projects to consider for estimation, and the analogy adaptation strategy for generating the estimation. In the effort estimation, usually the size measures have been exploited as the set of features characterizing the projects. It is worthwhile to point out that the selection of the similarity function and the number of analogies is a crucial decision. Many researchers suggested use of Euclidean distance as similarity measure and 1, 2, and 3 analogies to identify similar projects (Briand et al., 2000; Briand, El-Emam, Surmann, et al., 1999; Mendes, Counsell, & Mosley, 2002a; Mendes, Counsell, Mosley, Triggs et al., 2003). The analogy adaptation step allows for deciding how to obtain estimation after the most similar cases have been determined. Widely used adaptation techniques are the *nearest neighbour* (Briand, El-Emam, Surmann, et al., 1999; Mendes, Counsell, & Mosley, 2002a) the *mean of the closest analogies* (Mendes, Counsell, & Mosley, 2002a; Mendes, Counsell, Mosley, Triggs, et al., 2003; Myrtveit & Stensrud, 1999), the *inverse distance weighted mean,* and *inverse rank weighted mean* (Shepperd & Schofield, 2000).

Regression Tree (RT) is a variant of decision trees that can be used to approximate real-valued functions (Briand et al., 2000; Briand, El-Emam, Surmann, et al., 1999b; Mendes, Counsell, Mosley, Triggs et al., 2003). This technique takes as input a set of numerical variables (usually the size measures) and generates a binary tree predicting the value of the target variable (the development effort). In particular, the leaves of the binary tree suggest the values for the target variable on the base of the values of the predicting variables. The binary tree is built by recursively splitting the input data (i.e., the values of the predicting variables) into partitions. At the beginning, all data are associated to the root. Then, they are split in two parts, minimizing the sum of the squared deviations from the mean in the separated parts. At each split, the process determines the input variable to be used for splitting, and its values to associate to the left and right child nodes, respectively. Let us observe that each node has associated the mean value of the target variable. The process ends when, for each node, a minimum size, specified for the node by the user, is obtained. Subsequently, to determine the predicted value for the target variable, we start from the root node and then follow the right or left branch, based on the value of the splitting variable. We continue until a leaf node is reached, which contains the predicted value.

Validation Method and Evaluation Criteria

Validation is a crucial step in the empirical studies in order to verify whether or not the predicted efforts are useful estimations of the actual development efforts. A *cross validation* is widely employed to address it. In particular, this method partitions the data set into two randomly selected sets: the *training set* for model building and the *test set* for model evaluation.

To assess the acceptability of the derived estimations, summary measures, like *MMRE* and *Pred*(0.25) (Conte, Dunsmore, & Shen, 1986), together with *boxplots of (absolute) residuals* (Kitchenham, Pickard, MacDonnell, & Shepperd, 2001; Mendes, Counsell, & Mosley, 2005b). *MMRE* and *Pred*(0.25) are widely employed in the literature to assess the accuracy of effort estimation (see, for example, Briand, El-Emam, Surmann, et al., 1999; Briand, El-Emam, & Wieczorek, 1999, 2000; Briand & Wieczorek, 2002; Costagliola et al., 2006a; Costagliola, Martino, Ferrucci, Gravino, Tortora, & Vitiello, 2006b; Mendes, Counsell, & Mosley, 2003a, 2003b, 2003c; Mendes, Counsell, Mosley, Triggs, et al., 2003; Mendes & Kitchenham, 2004a, 2004b; Myrtveit. & Stensrud, 1999; Ruhe et al., 2003a, 2003b). In the following, we will briefly recall the main concepts underlying *MMRE* and *Pred*(0.25), and boxplots.

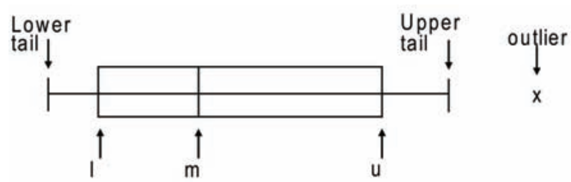
The *Magnitude of Relative Error* (Conte et al., 1986) is defined as $MRE = |EFHreal - EFHpred| / EFHreal$ where *EFHreal* and *EFHpred* are the actual and the predicted efforts, respectively. MRE has to be calculated for each observation in the data set. To have a cumulative measure of the error, all the MRE values are aggregated across all the observations using the mean and the median, thus obtaining two measures of the central tendency, known as Mean of *MRE* (*MMRE*), and Median MRE (*MdMRE*), where the latter is less sensitive to extreme values (Mendes, Counsell, Mosley, Triggs, et al., 2003).

The Prediction at level 0.25 (Conte et al., 1986) is defined as*Pred* (0.25) = k /Nwhere k is the number of observations whose *MRE* is less than or equal to 0.25, and N is the total number of observations. In other words, *Pred*(0.25) is a quantification of the predictions whose error is less than 25%. According to Conte et al. (1986), a good effort prediction model should have a *MMRE*≤0.25 and *Pred*(0.25)≥0.75, meaning that at least 75% of the predicted values should fall within 25% of their actual values.

Boxplots are widely employed in exploratory data analysis since they provide a quick visual representation to summarize the data using five numbers: the median, upper and lower quartiles, minimum and maximum values, and outliers (Kitchenham et al., 2001). The box of the plot is a rectangle with an end at each quartile and a line is drawn across the box at the sample median (*m* in Figure 1). The lower quartile (*l* in Figure 1) is determined considering the bottom half of the data, below the median, for example, by finding the median of this bottom data, while the upper quartile (*u* in Figure 1) is the median of the upper half of the data, above the median. The length of the box *d* is the interquartile range of the statistical sample. Lower tail is *u*+1.5**d* while *u*-1.5**d* is the Upper tail. Points at a distance from the median greater than 1.5 times the interquartile range represent potential outliers and are plotted individually.

In recent studies (see, for example, Costagliola et al., 2006b; Kitchenham et al., 2001; Mendes, Counsell, Mosley, Triggs, et al., 2003; Mendes, Counsell, & Mosley, 2005a, 2005b; Mendes & Kitchenham, 2004b; Ruhe et al., 2003b), the effectiveness of the obtained estimations of effort have been assessed by taking into account first the summary statistics and then the boxplots of absolute residuals, where residuals are calculated as (*EFHreal — EFHpred*).

Figure 1. The boxplot



In the following, we recall the main concepts of LR, CBR, and RT, and the methods widely adopted in the literature to validate the obtained estimations. Then, we will report on and discuss the most important empirical studies dealing with the estimation of Web development effort.

EMPIRICAL STUDIES

In the context of Web effort estimation, many empirical studies have been carried out aiming to address one of the following research issues:

- Verify the usefulness of size measures and cost factors for estimating Web application development effort.
- Verify the appropriateness of methods and techniques to provide effective effort estimations for Web applications.
- Verify the usefulness of cross-company data set for estimating Web application development effort.

In the following, we report on and discuss the empirical studies provided in the literature, taking into account the above research directions.

Empirical Studies Focused on Size Measures

In the last years some measures have been proposed to size Web Applications, such as *Web Objects* defined by Reifer (2000), *COSMIC-FFP* (COSMIC, 2005), the measures defined in the *Tukutuku* database by Mendes, Counsell, and Mosley (2003c), and *Length* and *Functional* measures investigated by Costagliola et al. (2006b)

Web Objects represent an extension of Function Points (FPs) (Albrecht, 1979), which are briefly recalled in the following. The current standard definition and counting procedure of the *FP* approach is reported in the IFPUG Counting Practices Manual (IFPUG, 2004). The measurement of the system size starts with the identification of all the functions, which can be of the following types: *external input*, *external output*, *external inquiry*, *internal logical file* and *external interface file*. The first three classes are considered transaction function types while the last two are considered data function types. Then, these identified functions are weighted in agreement with standard values specified in the Counting Practices Manual, by using their types and the level of their complexity. The *Web Objects* approach extends FPs by introducing four new Web-related components (*multimedia files*, *Web building blocks*, *scripts* and *links*), used as predictors together with the five traditional function types of FPs.

Ruhe et al. (2003a) were the first to investigate *Web Objects* by performing an empirical study based on a data set of 12 Web projects from industrial world, in order to establish whether or not this measure can be used to predict the development effort of Web applications in terms of person-hours, gathering interesting prediction results. In particular, these authors compared *Web Objects* with FPs and the results of the empirical analysis revealed that the model based on *Web Objects* presented significantly better prediction accuracy. In particular, they used LR as estimation technique and obtained an MMRE=0.24 and Pred(0.25)=0.67 for *Web Objects*, while the FPs produced a MMRE=0.33 and Pred(0.25)=0.42. These authors exploited 12 Web projects developed by a small-sized Australian software development company, which were very typical application in Web domain, for example, one for analysing and managing stock or transactions, several Web-based content management systems.

Successively, *Web Objects* measure has been investigated in other two studies (Di Martino, Ferrucci, Gravino, & Mendes, 2007; Ruhe et al., 2003b). In particular, Ruhe et al. (2003b) used *Web Objects* as size measure in the application of *WebCOBRA*, which is an adaptation of the *COBRA* method (Briand, El-Emam, & Bomarius, 1998) for the Web. They obtained better results than with LR, in particular MMRE=0.17, MdMRE=0.15, and Pred(0.25)=0.75. More details on *WebCOBRA* are reported in the next section. The empirical study performed by Di Martino et al. (2007) was aimed at comparing several size measures. By employing LR technique they obtained good results with *Web Objects*, in particular MMRE=0.17, MdMRE=0.11, and Pred(0.25)=0.80.

Common Software Metrics Consortium - Full Function Points (COSMIC-FFP) is a widely adopted method for sizing software, approved as an International Standard (ISO/IEC 19761:2003). It turns out to be particularly suited for real-time and/or multilayered software, whose complexity is mostly dominated by the need to manage large amounts of data (COSMIC, 2005). The basic idea underlying this approach is that, for many kinds of software, the biggest programming efforts are devoted to handle data movements, and thus their number can provide a meaningful sight of the system size. With the COSMIC-FFP method, a set of models, rules, and procedures have to be applied to the Functional User requirements (FUR) to obtain a numerical value, which represents the functional size of the software, expressed in terms of *Cosmic Functional Size Unit* (CFSU) (COSMIC, 2005). To apply the method "the COSMIC-FFP model […] requires FUR to be broken down into functional processes, each consisting of *data movements*, where a data movement moves a data group containing attributes of a single *object of interest*" (COSMIC, 2005).

Mendes, Counsell, and Mosley (2002a) applied the *COSMIC-FFP* measurement to Web hypermedia systems. Using data about 37 Web projects developed by academic students, they constructed an effort prediction model by applying LR. However, the derived model did not present reasonable prediction accuracy (MMRE < 0.50), and replications of the empirical study were highly recommended by authors to find possible biases in the collection of the data and/or in the application of the *COSMIC-FFP* method. Successively, Costagliola et al. (2006a) applied *COSMIC-FFP* taking into account dynamic aspects of Web applications. The *COSMIC-FFP* method was evaluated by using 44 Web projects (mainly Web portals, e-commerce sites, etc.), developed by academic students. The prediction models obtained by applying LR provided a good level of accuracy (MMRE=0.15, MdMRE=0.10, and Pred(0.25)= 0.75).

Tukutuku database is part of the Tukutuku project, which aims to collect data about Web applications to be used to develop Web effort estimation models and to benchmark productivity across and within Web Companies (Mendes, Counsell, & Mosley, 2003c). Each Web project is characterized by 25 variables related to the application and its development process, such as *Web pages*, *Images*, *Features reused without any adaptation*, and so forth. The complete list can be found in Mendes, Counsell, and Mosley (2005a). These size measures have been obtained from several empirical investigations performed by Mendes, Counsell, and Mosley (2001, 2002a, 2003a, 2003b, 2003c) and Mendes, Counsell, Mosley, Triggs et al. (2002, 2003). These studies highlighted that the employed measures can be profitably exploited to predict effort since the best estimations (obtained with LR and CBR) were characterized by MMRE values less than 0.25 and Pred(0.25) values greater than 0.75. In particular, the final set of size measures and cost drivers included in the Tukutuku database have been defined from the results of a survey investigation (Mendes, Counsell, & Mosley, 2005a), using data from 133 online Web forms aimed at giving quotes on Web development projects. In addition, these measures and cost drivers have also been confirmed by an established Web company and a second survey involving 33 Web companies in New Zealand. Several empirical studies have been carried out to assess the effectiveness of these size measures (Mendes & Kitchenham, 2004a; Mendes, Counsell, & Mosley, 2005a; Mendes, Di Martino, Ferrucci, & Gravino, 2007). Mendes Counsell, and Mosley (2005c) also presented a survey literature of hypermedia and Web size measures proposed in recent papers and classifies the analyzed studies according to a proposed taxonomy. The aim was to provide a mean for classifying and understanding the body of knowledge about Web size measures and their employing for effort estimation.

Costagliola et al. (2006b) investigated two sets of size measures: *Length* and *Functional* measures. *Length* measures were derived from both previous research (Mendes, Counsell, & Mosley, 2001, 2002a) and interviews with the company's project managers. The set of *Length* measures includes *Web Pages*, *Media*, *Scripts and Application*, and so forth (the complete list can be found in Costagliola et al., 2006b). As for the *Functional* measures, Costagliola et al. (2006b) used the nine components that are part of *Web Objects*. These size measures were compared by exploiting data from 15 Web projects provided by an Italian small-medium sized company whose core business is the development of enterprise information systems, mainly for local and central government. The company is highly specialized in the design, development and management of solutions for Web portals, enterprise intranet/extranet applications (such as content-ware, e-commerce, work-flow managers, etc.), and Geographical

Information Systems. The 15 Web applications employed in that case study are in several domains, such as e-government, e-banking, Web portals, and intranet applications. The results of the empirical study revealed that *Length* measures provided better estimates when using CBR (i.e., *MMRE*=0.15 and *Pred*(0.25)=0.73), while *Functional* measures provided better estimates when using LR (*MMRE*=0.21 and *Pred*(0.25)=0.73). However, their analysis suggested that there were no significant differences in the estimations and the residuals obtained with *Length* measures and *Functional* measures. Successively, Di Martino et al. (2007) compared the following size measures: *Web Objects* proposed by Reifer (2000), the *Length* and *Functional* measures used by Costagliola et al. (2006b), the *Tukutuku* measures proposed by Mendes, Counsell, and Mosley (2003c). As a data set, they exploited the Web projects employed in Costagliola et al. (2006b). The empirical results showed that all the measures provided good predictions in terms of *MMRE*, *MdMRE*, and *Pred*(0.25) and the study largely confirmed the results of previous work (Costagliola et al., 2006b). Moreover, the analysis of residuals suggested that *Length* measures and *Web Objects* presented significantly superior predictions than *Functional measures* when estimates are obtained using LR; however all presented similar predictions to the *Tukutuku* measures.

Finally, we would recall other two works. Abrahão and Pastor (2003) proposed the *OOmFPWeb* method, which maps the *FP* concepts into the primitives used in the conceptual modeling phase of *OOWS*, a method for producing software for the Web (Abrahão, Fons, & Pastor, 2001). In a recent work (Abrahão, Pastor, & Poels, 2004), a preliminary evaluation of the *OOmFPWeb* has been provided.

Baresi and Morasca (2003) focused their attention on Web applications automatically generated from a design model expressed in terms of W2000. They defined several measures on the basis of attributes obtained from design artifacts, and conducted empirical studies aiming to identify the attributes that may be related to the effort required for designing Web applications. This empirical study involved the students of an advanced university class on modeling Web applications, enrolled in engineering curricula, and employed Linear Regression. The empirical results suggested that the size of the information model, as well as the reuse level and the characteristics of the navigation model, influence the total design effort. It is worth noting that these studies differ from the ones presented above since Baresi and Morasca (2003) focused on design effort and not on the total effort.

Empirical Studies Focused on Estimation Techniques

Several empirical studies have been carried out to analyze the effectiveness of LR, CBR, and RT in the case of desktop applications. In particular, Briand, El-Emam, Surmann, et al. (1999) and Briand, El-Emam, and Wieczorek (2000) applied LR, RT, and CBR, using 1 and 2 analogies, and combinations of these techniques. Their results pointed out that LR is better than CBR in predicting efforts. To date, numerous studies have investigated these estimation techniques for Web effort estimation (e.g., Costagliola et al., 2006a, 2006b; Di Martino et al., 2007; Mendes, Counsell, & Mosley, 2001, 2002a, 2003a, 2003c, 2005b; Mendes, Counsell, Mosley, Triggs et al., 2002, 2003; Mendes & Kitchenham, 2004a, 2004b, Mendes & Mosley, 2002; Ruhe et al., 2003a;).

In the following, we focus our attention on the studies that have employed LR, CBR, and RT (Costagliola et al., 2006b; Di Martino et al., 2007; Mendes, Counsell, Mosley, Triggs et al., 2002, 2003; Mendes & Mosley, 2002;).

Costagliola et al. (2006b) performed an empirical analysis employing LR, CBR, and RT and exploiting *Length* and *Functional* measures (described in the previous section). They found that none of the effort estimation techniques used in their study was statistically significantly superior to others; however, the three accuracy measures used (i.e., MMRE, MdMRE, and Pred(0.25)) suggested that LR presented overall the best and the worst accuracy using elements of *Functional* and *Length* size measures, respectively. The study conducted by Di Martino et al. (2007) largely confirmed the above results, revealing that both LR and CBR can be profitably exploited to predict Web application development effort. Mendes, Counsell, Mosley, Triggs et al. (2002, 2003) exploited a data set of 37 Web projects developed by academic students and highlighted that LR models generally gave statistically significant better results than CBR. On the contrary, the case study carried out by Di Martino et al. (2007) revealed that there is no significant difference between estimations obtained with CBR and those obtained with the LR. As for CBR Mendes, Counsell, Mosley, Triggs et al. (2003) considered three choices for number of analogies (1, 2, and 3) and three choices for the analogy adaptation (mean of k analogies, inverse rank weighted mean, and median of k analogies). The best result was achieved by using weighted distance and 1 analogy. Moreover, in another work on the analysis of the CBR, Mendes and Mosley (2002) proved that the use of adaptation rules presented statistically better prediction accuracy than their counterparts than did not use adaptation. Costagliola et al. (2006b) obtained the best results with CBR using 2 analogies and inverse distance weighted mean as adaptation strategy (employing *Functional* measures), while Di Martino et al. (2007) obtained the best results with CBR using 2 analogies and the mean of 2 analogies as adaptation strategy (with *Web Objects* as size measure) and 2 analogies and the inverse distance weighted mean as adaptation strategy (for *COSMIC-FFP* as size measure).

Morever, we want to recall two works that have proposed cost estimation models specific for the Web, namely *WebMO* (Reifer, 2000) and *WebCOBRA* (Ruhe et al., 2003b).

WebMO is a direct extension of the COCOMO II Early Design model (Bohem, 1981). The idea underlying the approach is to adapt the existing effort estimation methods in order to use them in the context of Web applications. As an extension of the Early Design of the COCOMO II method, *WebMO* does not require a deep knowledge about the influence of cost drivers on the development process, and generic cost drivers can be defined in order to estimate in the early phase of the development process those features which will be more influent on the final development effort (Reifer, 2000). Except the empirical analysis performed by Reifer in order to calibrate the *WebMO*, to the best of our knowledge no empirical studies have been carried out employing this method.

WebCOBRA is an adaptation to the Web domain of the COBRA (COst estimation, Benchmarking and Risk Analysis) method (Briand et al., 1998). The key issue of this method is to use both expert knowledge and few past project data to obtain a COBRA instance, named COBRA model, which results specifically tailored for the intended software development context. In order to obtain a COBRA model, information about Project Characteristics, such as project type, application domain, and so forth, the Size Measure, calculated in a consistent way among all projects, and some Cost Drivers, specifying the resources expected to influence the development effort have to be determined. These three factors form the causal model, which is intended to describe all the cost factors involved in the project development. The causal model, together with the past project data, define a resulting COBRA model. The past project data are used to define the relationships between cost overhead and cost, for the considered software development context. Ruhe et al. (2003b) derived the *WebCOBRA* approach by modifying the causal model, and by adopting the *Web Objects* method to measure the size of the software. Furthermore, to evaluate the prediction accuracy of the *WebCOBRA* model, they performed an empirical study by exploiting the 12

Web projects developed by an Australian software development company and obtained *MMRE*=0.17, *MdMRE*=0.15, and *Pred*(0.25)=0.75. These results are better than those they obtained in Ruhe et al. (2003a) by employing as estimation technique LR (see the previous section). In the future, it could be interesting to exploit both *COSMIC-FFP* and *Web Objects* measures in the application of the *WebCOBRA* method using a larger industrial data set and compare the obtained results.

Empirical Studies Focused on Cross-Company Data Set

Recently, in the context of the Web, few studies have investigated whether a cross-company data set (i.e., a data set containing project data from several software companies) can provide estimates for the new projects comparable to the one obtained from single-company data sets (i.e., data sets containing project data from a single company), which deals with the generalization of the results achieved in a given context (Mendes et al., 2007; Mendes & Kitchenham, 2004a, 2004b).

The use of a cross-company data set seems particularly useful for companies that do not have their own data on past projects from which to obtain their estimates, or that have data on projects developed in different application domains and/or technologies (Mendes et al., 2007; Mendes & Kitchenham, 2004a, 2004b). The goal of these studies is to investigate how successful is a cross-company effort model to estimate effort for Web projects that belong to a single company and were not used to build the cross-company model, and compared to a single-company effort model. The data sets employed in these three studies were obtained from the Tukutuku database, and the effort estimates were obtained by means of LR and CBR. About the results, these empirical studies have revealed that the predictions based on the single-company model were significantly more accurate than those based on the cross-company ones. In particular, in the study presented by Mendes et al. (2007), the accuracy of estimates obtained using the cross-company model obtained with LR shows low prediction accuracy, with a quite high MMRE (85.86%), and an extremely poor Pred(25) (6.67%), far from the thresholds suggested by Conte et al. (1986). The same pattern was present for predictions obtained using CBR: MMRE is 92.54% and Pred(25) is 0%, both really poor. These results corroborate those obtained by Mendes and Kitchenham (2004b).

It is worth noting that the majority of the empirical studies provided in the literature, and reported in the previous sections, exploited data coming from a single company. On one hand, this can lead to more accurate results, since the data collection task can be carried out in a more controlled fashion than in a cross-company scenario, as recognized by Kitchenham, Mendes, Travassos, and Guilherme (2007). But, on the other hand, the obtained results might not hold in other industrial contexts. In particular, the models obtained with data coming from a given company/domain might not supply accurate predictions when used in different companies/domains, where some recalibrations could be necessary as suggested by Mendes and Kitchenham (2004b).

CONCLUSION

In this chapter, we have reported on and discussed the most significant empirical studies undertaken so far and aimed at verifying:

- The usefulness of size measures and cost factors for estimating Web application development effort.
- The appropriateness of methods and techniques to provide effective effort estimations for Web applications.
- The usefulness of cross-company data set for estimating Web application development effort.

The analysis has revealed that several size measures have been successfully employed to estimate the size and the effort of Web applications. However, further empirical investigations are needed to achieve widely accepted size measures for the Web. Regarding the employed estimation techniques, LR and CBR, widely adopted in Software Engineering to estimate effort of software projects, have also obtained interesting results in the context of Web.

FUTURE RESEARCH DIRECTIONS

It is worth noting that only few empirical studies in the field of Web effort estimation exploited industrial data sets (Costagliola et al., 2006b; Di Martino et al., 2007; Mendes, Counsell, & Mosley, 2005a, 2005b, 2005c; Mendes & Kitchenham, 2004a, 2004b; Ruhe et al., 2003a, 2003b). This is partly due to the lack of "meaningful" data sets publicly available that allow researchers to perform investigations. It is worth noting that the "quality" of the data set used can deeply influence the results of the study. Indeed, if data is not properly collected, or if it is not representative of a wider context, the effectiveness of the empirical study is heavily reduced. In the field of software engineering, these recommendations are usually fitted by using data coming from the industrial world, collected in a correct and consistent way (see, for example, Briand et al., 2000; Briand, El-Emam, & Surmann, et al., 1999; Greves & Schreiber, 1996; Jeffery et al., 2000; Mendes, Lokan et al., 2005). However, in the Web domain, it may be difficult to obtain large and significant data sets from the industrial world, since the time required to accumulate enough data on past projects may be very high, as well as the fact that technologies evolve very quickly, making old data useless (Mendes & Kitchenham, 2004b). Thus, in the future, Web companies should pay more attention to cope with the problem of collecting data from past projects in order to exploit them for effort estimation in several and different contexts.

Moreover, the research in the future should also focus on designing and developing tools able to automatically obtain information on cost factors and size measures. In particular, these tools should allow researchers to collect past projects data from companies developing Web applications employing different methods, techniques, and technologies with the aim of supporting managers in the identification of the most effective measures and estimation techniques to be applied in several and different contexts. Other techniques should also be investigated for effort estimation, such as fuzzy strategies, and the achieved results should be compared with those obtained by employing LR and CBR. Finally, future work should also cover the identification and investigation of size measures to be used not only in the early phase of development process but also in other phases, such as testing and maintenance.
